Local recurrence is easily detected by physical examination, by the patient himself or his physician. Patient education is an essential part of follow-up and the patient should be urged to visit a specialist if any changes are seen.

7.1.3 Regional recurrence

Most regional recurrences occur during the first two years after treatment, irrespective of whether surveillance or invasive nodal staging were used. Although unlikely, regional recurrence can occur later than two years after treatment. It is therefore advisable to continue follow up in these patients [197]. The highest rate of regional recurrence (9%) occurs in patients managed by surveillance, while the lowest is in patients who have undergone invasive nodal staging by modified inguinal lymphadenectomy or DSNB and whose lymph nodes were negative (2.3%).

The use of US and fine needle aspiration cytology (FNAC) in suspicious cases has improved the early detection rate of regional recurrence [76, 198, 199]. There are no data to support the routine use of CT or MRI for the follow-up of inguinal nodes.

Patients who have had surgery for lymph node metastases without adjuvant treatment have an increased risk of regional recurrence of 19% [87]. Regional recurrence requires timely treatment by radical inguinal lymphadenectomy and adjuvant chemotherapy (see Section 6).

7.1.4 Guidelines for follow-up in penile cancer

	Interval of follow-up		**Examinations and investigations**	**Minimum duration of follow-up**	**Strength rating**
	Years one to two	Years three to five			
Recommendations for follow-up of the primary tumour					
Penile-preserving treatment	Three months	Six months	Regular physician or self-examination. Repeat biopsy after topical or laser treatment for penile intraepithelial neoplasia.	Five years	Strong
Amputation	Three months	One year	Regular physician or self-examination.	Five years	Strong
Recommendations for follow-up of the inguinal lymph nodes					
Surveillance	Three months	Six months	Regular physician or self-examination.	Five years	Strong
pN0 at initial treatment	Three months	One year	Regular physician or self-examination. Ultrasound with fine-needle aspiration biopsy optional.	Five years	Strong

pN+ at initial treatment	Three months	Six months	Regular physician or self-examination. Ultrasound with fine-needle aspiration cytology optional, computed tomography/ magnetic resonance imaging optional.	Five years	Strong

7.2 Quality of life

*7.2.1 **Consequences after penile cancer treatment***

In patients with long-term survival after penile cancer treatment, sexual dysfunction, voiding problems and cosmetic penile appearance may adversely affect the patient's QoL [200]. However, there is very little data on sexual function and QoL after treatment for penile cancer. In particular, there is heterogeneity of the psychometric tools used to assess QoL outcomes and further research is needed to develop disease-specific patient reported outcome measures for penile cancer.

Comparative studies

There are only two comparative studies in the literature reporting on the health-related quality of life (HRQoL) outcomes following surgery for localised penile cancer. One study compared wide local excision with glansectomy [201]. Among 41 patients there was reduction in post-operative International Index of Erectile Function (IIEF) and the authors concluded that local excision led to better sexual outcomes than glansectomy. In another study of 147 patients, the IIEF-15, the SF36 Health Survey and the Impact of Cancer questionnaire were used [202].

Compared to an age-matched population sample, men after partial penectomy reported significantly more problems with orgasm, cosmesis, life interference and urinary function than those who had undergone penile-sparing surgery (83% vs. 43%, $p < 0.0001$). Interestingly, there were no differences in erectile function, sexual desire, intercourse satisfaction or overall sexual satisfaction.

*7.2.2 **Sexual activity and quality of life after laser treatment***

A retrospective interview-based Swedish study after laser treatment for penile PeIN [104] in 58 out of 67 surviving patients with a mean age of 63 years, of whom 46 participated, reported a marked decrease in some sexual practices, such as manual stimulation, caressing and fellatio, but a general satisfaction rate with life overall and sexuality which was similar to that of the general Swedish population.

A large study on CO_2 laser treatment of penile cancer in 224 patients reported no problems with erectile or sexual function following treatment [91]. In another study [107], no sexual dysfunction occurred in nineteen patients treated.

*7.2.3 **Sexual activity after glans resurfacing***

In one study with ten patients [111], 7/10 completed questionnaires (IIEF-5 and a non-validated 9-item questionnaire) at six months. The median IIEF-5 score was 24 (no erectile dysfunction). All patients who were sexually active before treatment were active after three to five months, 7/7 stated that the sensation at the tip of their penis was either no different or better after surgery, and 5/7 patients felt that their sex life had improved. Overall patient satisfaction with glans resurfacing was high.

*7.2.4 **Sexual activity after glansectomy***

Two studies reported sexual function after glansectomy [112, 113]. In one (n = 68) with unclear methodology [113], 79% did not report any decline in spontaneous erection, rigidity or penetrative capacity after surgery, and 75% reported recovery of orgasm. In the other study [114], all twelve patients had returned to 'normal' sexual activity one month after surgery.

*7.2.5 **Sexual function after partial penectomy***

Sexual function after partial penectomy was reported by three studies [203-205]. In one with 18 patients with a mean age of 52 years, the IIEF scores were significantly worse for all domains of sexual function after surgery [203] and 55.6% of patients had erectile function that allowed sexual intercourse. In patients who did not resume sexual activity, 50% were ashamed of their small penis and missing glans, while another third blamed surgical complications. Of those who had resumed sexual intercourse, 66.7% reported the same frequency and level of sexual activity as before surgery, while 72.2% continued to have ejaculation and orgasm every time with sexual activity. Overall, only 33.3% maintained their pre-operative frequency of sexual intercourse and were satisfied with their sex life.

In another study, an 'Overall Sexual Functioning Questionnaire' was used in 14 patients with a median time of 11.5 months after surgery (range 6-72) [204]. Prior to surgery, all patients had had normal erectile function and intercourse at least once a month. In 9/14 patients, sexual function was 'normal' or 'slightly decreased', while 3/14 had had no sexual intercourse since surgery. Alei *et al.* reported an improvement in erectile function over time [205]. In a report of 25 patients after partial penectomy and neoglans formation, the IIEF-5, Quality of Erection Questionnaire (QEQ), Erectile Dysfunction Inventory of Treatment Satisfaction (EDITS) and Self-Esteem and Relationship (SEAR) were used. This study reported a high percentage of patient and partner satisfaction with surgical treatment and recovery of sexual function, self-esteem, and overall relationship satisfaction [206].

*7.2.6 **Quality of life and sexual function after total penectomy***

In ten patients with penile cancer evaluated after total amputation of the penis, there were significant effects on sexual life and overall QoL, although there were no negative implications in terms of partner relationships, self-assessment or the evaluation of masculinity [207].

*7.2.7 **Quality of life after partial penectomy***

Several qualitative and quantitative instruments have been used to assess 'psychological behaviour and adjustment' and 'social activity' as QoL indicators [204, 208]. Patient-reported fears were those of mutilation, loss of sexual pleasure and of cancer death and what this would mean for their families. The study reported no significant levels of anxiety and depression on the General Health Questionnaire-12 and the Hospital Anxiety and Depression Scale. 'Social activity' remained the same after surgery in terms of living conditions, family life and social interactions.

7.3 Total phallic reconstruction

There is very limited data about total phallic reconstruction following full or near-total penile amputation [137, 209, 210]. Although it is not possible to restore function without a penile prosthesis, cosmetically acceptable results can be obtained.

7.4 Specialised care

Since penile cancer is rare, patients should be referred to a centre with experience and expertise in local treatment, pathological diagnosis, chemotherapy and psychological support for penile cancer patients. Some countries have centralised the care of penile cancer patients (Sweden, Denmark, the Netherlands, the UK).

9. CONFLICT OF INTEREST

All members of the Penile Cancer Guidelines working group have provided disclosure statements of all relationships that they have that might be perceived as a potential source of a conflict of interest. This information is publicly accessible through the European Association of Urology website: http://uroweb.org/guideline/penile-cancer/.

This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

10. CITATION INFORMATION

The format in which to cite the EAU Guidelines will vary depending on the style guide of the journal in which the citation appears. Accordingly, the number of authors or whether, for instance, to include the publisher, location, or an ISBN number may vary.

The compilation of the complete Guidelines should be referenced as:
EAU Guidelines. Edn. presented at the EAU Annual Congress Amsterdam, 2020. ISBN 978-94-92671-07-3.

If a publisher and/or location is required, include:
EAU Guidelines Office, Arnhem, The Netherlands. http://uroweb.org/guidelines/compilations-of-all-guidelines/

References to individual guidelines should be structured in the following way:
Contributors' names. Title of resource. Publication type. ISBN. Publisher and publisher location, year.

EAU Guidelines on

Management of Non-Neurogenic Male Lower Urinary Tract Symptoms (LUTS), incl. Benign Prostatic Obstruction (BPO)

S. Gravas (Chair), J.N. Cornu, M. Gacci, C. Gratzke, T.R.W. Herrmann, C. Mamoulakis, M. Rieken, M.J. Speakman, K.A.O. Tikkinen

TABLE OF CONTENTS PAGE

1. INTRODUCTION

1.1 Aim and objectives

Lower urinary tract symptoms (LUTS) are a common complaint in adult men with a major impact on quality of life (QoL), and have a substantial economic burden. The present Guidelines offer practical evidence-based guidance on the assessment and treatment of men aged 40 years or older with various non-neurogenic benign forms of LUTS. The understanding of the LUT as a functional unit, and the multifactorial aetiology of associated symptoms, means that LUTS now constitute the main focus, rather than the former emphasis on Benign Prostatic Hyperplasia (BPH). It must be emphasised that clinical guidelines present the best evidence available to the experts. However, following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The EAU Non-neurogenic Male LUTS Guidelines Panel consists of an international group of experts with urological and clinical epidemiological backgrounds. All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website Uroweb: http://uroweb.org/guideline/treatment-of-non-neurogenic-male-luts/.

1.3 Available publications

A quick reference document, the Pocket Guidelines, is available in print and as an app for iOS and Android devices. These are abridged versions which may require consultation together with the full text version. All documents are accessible through the EAU website Uroweb: http://www.uroweb.org/guideline/treatment-of-non-neurogenic-male-luts/.

1.4 Publication history

The Non-neurogenic Male LUTS Guidelines was first published in 2000. The standard procedure for EAU Guidelines includes an annual assessment of newly published literature in the field to guide future updates. The 2020 document presents a limited update of the 2019 publication; the next update of the Non-neurogenic Male LUTS Guidelines will be presented in 2021.

2. METHODS

2.1 Introduction

For the 2020 Management of Non-Neurogenic Male LUTS Guidelines, new and relevant evidence was identified, collated and appraised through a structured assessment of the literature. A broad and comprehensive literature search, covering all sections of the Non-Neurogenic Male LUTS Guidelines was performed. The search was limited to studies representing high levels of evidence, i.e. systematic reviews with meta-analysis, randomised controlled trials (RCTs), and prospective non-randomised comparative studies, published in the English language. Databases searched included Medline, EMBASE, and the Cochrane Libraries, covering a time frame between April 30th 2018 and April 1st 2019. A total of 1,254 unique records were identified, retrieved and screened for relevance. A detailed search strategy is available online: http://www.uroweb.org/guideline/ treatment-of-non-neurogenic-male-luts/supplementary-material.

For each recommendation within the guidelines there is an accompanying online strength rating form, the bases of which is a modified GRADE methodology [1, 2]. Each strength rating form addresses a number of key elements namely:

1. the overall quality of the evidence which exists for the recommendation, references used in this text are graded according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [3];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact of patient values and preferences on the intervention;
6. the certainty of those patient values and preferences.

These key elements are the basis which panels use to define the strength rating of each recommendation. The strength of each recommendation is represented by the words 'strong' or 'weak' [4]. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and nature and variability of patient values and preferences.

Additional information can be found in the general Methodology section of this print, and online at the EAU website; http://www.uroweb.org/guideline/. A list of associations endorsing the EAU Guidelines can also be viewed online at the above address.

2.2 Review

The Non-Neurogenic Male LUTS Guidelines were peer reviewed prior to publication in 2016.

2.3 Patients to whom the guidelines apply

Recommendations apply to men aged 40 years or older who seek professional help for LUTS in various non-neurogenic and non-malignant conditions such as LUTS/Benign Prostatic Obstruction (BPO), detrusor overactivity/overactive bladder (OAB), or nocturnal polyuria. Men with other contexts of LUT disease (e.g. concomitant neurological diseases, young age, prior LUT disease or surgery) usually require a more extensive work-up, which is not covered in these Guidelines, but may include several tests mentioned in the following sections. EAU Guidelines on Neuro-Urology, Urinary Incontinence, Urological Infections, Urolithiasis, or malignant diseases of the LUT have been developed by other EAU Guidelines Panels and are available online: www.uroweb.org/guidelines/.

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOPHYSIOLOGY

Lower urinary tract symptoms can be divided into storage, voiding and post-micturition symptoms [5], they are prevalent, cause bother and impair QoL [6-9]. An increasing awareness of LUTS and storage symptoms in particular, is warranted to discuss management options that could increase QoL [10]. Lower urinary tract symptoms are strongly associated with ageing [6, 7], associated costs and burden are therefore likely to increase with future demographic changes [7, 11]. Lower urinary tract symptoms are also associated with a number of modifiable risk factors, suggesting potential targets for prevention (e.g. metabolic syndrome) [12]. In addition, men with moderate-to-severe LUTS may have an increased risk of major adverse cardiac events [13].

Most elderly men have at least one LUTS [7]; however, symptoms are often mild or not very bothersome [9, 10, 14]. Lower urinary tract symptoms can progress dynamically: for some individuals LUTS persist and progress over long time periods, and for others they remit [7]. Lower urinary tract symptoms have traditionally been related to bladder outlet obstruction (BOO), which is often caused by benign prostatic enlargement (BPE) resulting from the histologic condition of BPH [5, 8]. However, increasing numbers of studies have shown that LUTS are often unrelated to the prostate [7, 15]. Bladder dysfunction may also cause LUTS, including detrusor overactivity/OAB, detrusor underactivity/underactive bladder, as well as other structural or functional abnormalities of the urinary tract and its surrounding tissues [15]. Prostatic inflammation also appears to play a role in BPH pathogenesis and progression [16, 17]. In addition, many non-urological conditions also contribute to urinary symptoms, especially nocturia [7].

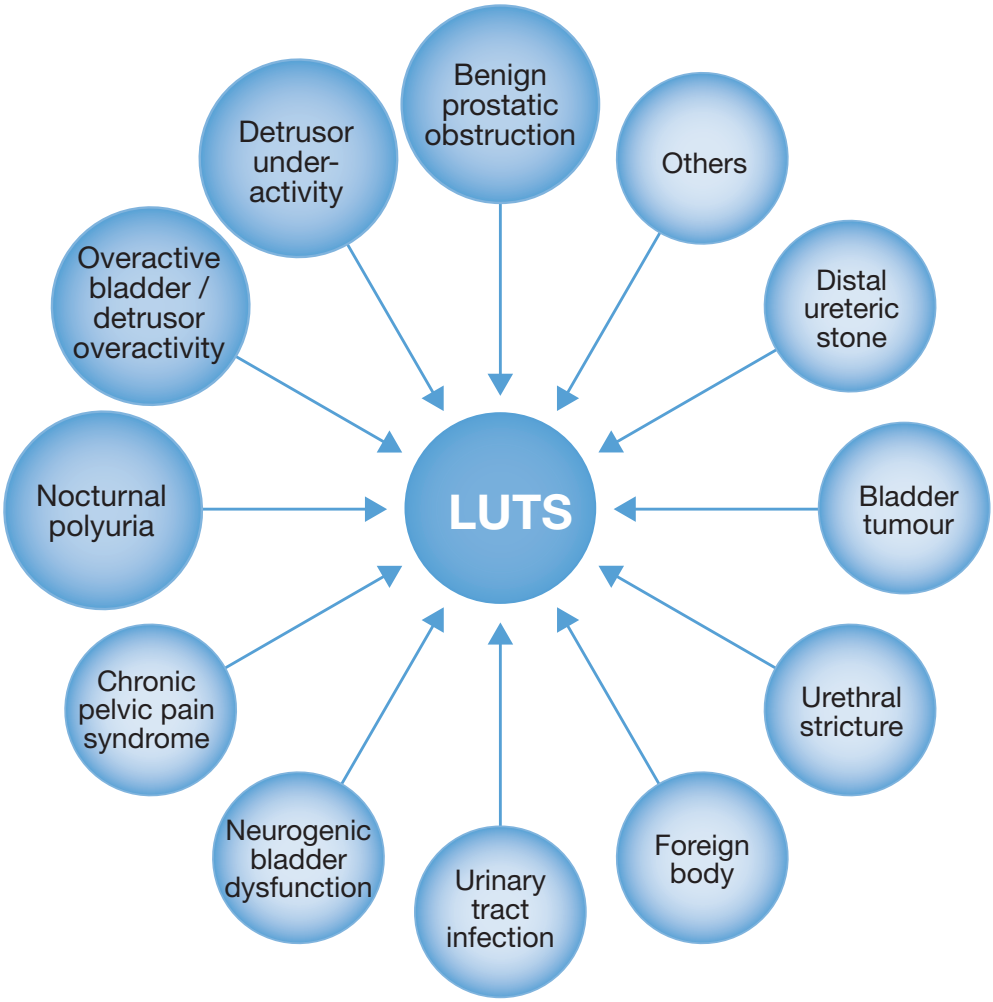
The definitions of the most common conditions related to male LUTS are presented below:

- Acute retention of urine is defined as a painful, palpable or percussible bladder, when the patient is unable to pass any urine [5].
- Chronic retention of urine is defined as a non-painful bladder, which remains palpable or percussible after the patient has passed urine. Such patients may be incontinent [5].
- Bladder outlet obstruction is the generic term for obstruction during voiding and is characterised by increasing detrusor pressure and reduced urine flow rate. It is usually diagnosed by studying the synchronous values of flow-rate and detrusor pressure [5].
- Benign prostatic obstruction is a form of BOO and may be diagnosed when the cause of outlet obstruction is known to be BPE [5]. In the Guidelines the term BPO or BOO is used as reported by the original studies.
- Benign prostatic hyperplasia is a term used (and reserved) for the typical histological pattern, which defines the disease.

- Detrusor overactivity (DO) is a urodynamic observation characterised by involuntary detrusor contractions during the filling phase which may be spontaneous or provoked [5].
- Overactive bladder syndrome is characterised by urinary urgency, with or without urgency urinary incontinence, usually with increased daytime frequency and nocturia, if there is no proven infection or other obvious pathology [18].

Figure 1 illustrates the potential causes of LUTS. In any man complaining of LUTS, it is common for more than one of these factors to be present.

Figure 1: Causes of male LUTS



4. DIAGNOSTIC EVALUATION

Tests are useful for diagnosis, monitoring, assessing the risk of disease progression, treatment planning, and the prediction of treatment outcomes. The clinical assessment of patients with LUTS has two main objectives:

- to identify the differential diagnoses, since the origin of male LUTS is multifactorial, the relevant EAU Guidelines on the management of applicable conditions should be followed;
- to define the clinical profile (including the risk of disease progression) of men with LUTS in order to provide appropriate care.

4.1 Medical history

The importance of assessing the patient's history is well recognised [19-21]. A medical history aims to identify the potential causes and relevant comorbidities, including medical and neurological diseases. In addition, current medication, lifestyle habits, emotional and psychological factors must be reviewed. The Panel recognises the need to discuss LUTS and the therapeutic pathway from the patient's perspective. This includes reassuring the patient that there is no definite link between LUTS and prostate cancer (PCa) [22, 23].

As part of the urological/surgical history, a self-completed validated symptom questionnaire (see section 4.2) should be obtained to objectify and quantify LUTS. Voiding diaries are particularly beneficial when assessing patients with nocturia and/or storage symptoms (see section 4.3). Sexual function should also be assessed, preferably with validated symptom questionnaires such as the International Index for Erectile Function (IIEF) [24].

Summary of evidence	LE
A medical history is an integral part of a patient's medical evaluation.	4
A medical history aims to identify the potential causes of LUTS as well as any relevant comorbidities and to review the patient's current medication and lifestyle habits.	4

Recommendation	Strength rating
Take a complete medical history from men with LUTS.	Strong

4.2 Symptom score questionnaires

All published guidelines for male LUTS/BPH recommend using validated symptom score questionnaires [19, 21]. Several questionnaires have been developed which are sensitive to symptom changes and can be used to monitor treatment [25-31]. Symptom scores are helpful in quantifying LUTS and in identifying which type of symptoms are predominant; however, they are not disease-, or age-specific. A systematic review (SR) evaluating the diagnostic accuracy of individual symptoms and questionnaires, compared with urodynamic studies (the reference standard), for the diagnosis of BOO in males with LUTS found that individual symptoms and questionnaires for diagnosing BOO were not significantly associated with one another [32].

4.2.1 The International Prostate Symptom Score (IPSS)

The IPSS is an eight-item questionnaire, consisting of seven symptom questions and one QoL question [26]. The IPSS score is categorised as 'asymptomatic' (0 points), 'mildly symptomatic' (1-7 points), 'moderately symptomatic' (8-19 points), and 'severely symptomatic' (20-35 points). Limitations include lack of assessment of incontinence, post-micturition symptoms, and bother caused by each separate symptom.

4.2.2 The International Consultation on Incontinence Questionnaire (ICIQ-MLUTS)

The ICIQ-MLUTS was created from the International Continence Society (ICS) Male questionnaire. It is a widely used and validated patient completed questionnaire [27]. It contains thirteen items, with subscales for nocturia and OAB, and is available in seventeen languages.

4.2.3 Danish Prostate Symptom Score (DAN-PSS)

The DAN-PSS [30] is a symptom score used mainly in Denmark and Finland. The ICIQ-MLUTS and DAN-PSS measure the bother of each individual LUTS.

Summary of evidence	LE
Symptom questionnaires are sensitive to symptom changes.	3
Symptom scores can quantify LUTS and identify which types of symptoms are predominant; however, they are not disease- or age-specific.	3

Recommendation	Strength rating
Use a validated symptom score questionnaire including bother and quality of life assessment during the assessment of male LUTS and for re-evaluation during and/or after treatment.	Strong

4.3 Frequency volume charts and bladder diaries

The recording of volume and time of each void by the patient is referred to as a frequency volume chart (FVC). Inclusion of additional information such as fluid intake, use of pads, activities during recording, or symptom scores is termed a bladder diary [5]. Parameters that can be derived from the FVC and bladder diary include: day-time and night-time voiding frequency, total voided volume, the fraction of urine production during the night (nocturnal polyuria index), and volume of individual voids.

The mean 24-hour urine production is subject to considerable variation. Likewise, circumstantial influence and intra-individual variation cause FVC parameters to fluctuate, though there is comparatively little

data [33, 34]. The FVC/bladder diary is particularly relevant in nocturia, where it underpins the categorisation of underlying mechanism(s) [35-37]. The use of FVCs may cause a 'bladder training effect' and influence the frequency of nocturnal voids [38].

The duration of the FVC/bladder diary needs to be long enough to avoid sampling errors, but short enough to avoid non-compliance [39]. A SR of the available literature recommended FVCs should continue for three or more days [40].

Summary of evidence	LE
Frequency volume charts and bladder diaries provide real-time documentation of urinary function and reduce recall bias.	3
Three and seven day FVCs provide reliable measurement of urinary symptoms in patients with LUTS.	2b

Recommendations	Strength rating
Use a bladder diary to assess male LUTS with a prominent storage component or nocturia.	Strong
Tell the patient to complete a bladder diary for at least three days.	Strong

4.4 Physical examination and digital-rectal examination

Physical examination particularly focusing on the suprapubic area, the external genitalia, the perineum and lower limbs should be performed. Urethral discharge, meatal stenosis, phimosis and penile cancer must be excluded.

4.4.1 Digital-rectal examination and prostate size evaluation

Digital-rectal examination (DRE) is the simplest way to assess prostate volume, but the correlation to prostate volume is poor. Quality-control procedures for DRE have been described [41]. Transrectal ultrasound (TRUS) is more accurate in determining prostate volume than DRE. Underestimation of prostate volume by DRE increases with increasing TRUS volume, particularly where the volume is > 30 mL [42]. A model of visual aids has been developed to help urologists estimate prostate volume more accurately [43]. One study concluded that DRE was sufficient to discriminate between prostate volumes > or < 50 mL [44].

Summary of evidence	LE
Physical examination is an integral part of a patient's medical evaluation.	4
Digital-rectal examination can be used to assess prostate volume; however, the correlation to actual prostate volume is poor.	3

Recommendation	Strength rating
Perform a physical examination including digital rectal examination in the assessment of male LUTS.	Strong

4.5 Urinalysis

Urinalysis (dipstick or sediment) must be included in the primary evaluation of any patient presenting with LUTS to identify conditions, such as urinary tract infections (UTI), microhaematuria and diabetes mellitus. If abnormal findings are detected further tests are recommended according to other EAU Guidelines, e.g. Guidelines on urinary tract cancers and urological infections [45-48].

Urinalysis is recommended in most Guidelines in the primary management of patients with LUTS [49, 50]. There is limited evidence, but general expert consensus suggests that the benefits outweigh the costs [51]. The value of urinary dipstick/microscopy for diagnosing UTI in men with LUTS without acute frequency and dysuria has been questioned [52].

Summary of evidence	LE
Urinalysis (dipstick or sediment) may indicate a UTI, proteinuria, haematuria or glycosuria requiring further assessment.	3
The benefits of urinalysis outweigh the costs.	4

Recommendation	Strength rating
Use urinalysis (by dipstick or urinary sediment) in the assessment of male LUTS.	Strong

4.6 Prostate-specific antigen (PSA)

4.6.1 PSA and the prediction of prostatic volume

Pooled analysis of placebo-controlled LUTS/BPH trials showed that PSA has a good predictive value for assessing prostate volume, with areas under the curve (AUC) of 0.76-0.78 for various prostate volume thresholds (30 mL, 40 mL, and 50 mL). To achieve a specificity of 70%, whilst maintaining a sensitivity between 65-70%, approximate age-specific criteria for detecting men with prostate glands exceeding 40 mL are PSA > 1.6 ng/mL, > 2.0 ng/mL, and > 2.3 ng/mL, for men with BPH in their 50s, 60s, and 70s, respectively [53].

A strong association between PSA and prostate volume was found in a large community-based study in the Netherlands [54]. A PSA threshold value of 1.5 ng/mL could best predict a prostate volume of > 30 mL, with a positive predictive value (PPV) of 78%. The prediction of prostate volume can also be based on total and free PSA. Both PSA forms predict the TRUS prostate volume (± 20%) in > 90% of the cases [55, 56].

4.6.2 PSA and the probability of PCa

The role of PSA in the diagnosis of PCa is presented by the EAU Guidelines on Prostate Cancer [57]. The potential benefits and harms of using serum PSA testing to diagnose PCa in men with LUTS should be discussed with the patient.

4.6.3 PSA and the prediction of BPO-related outcomes

Serum PSA is a stronger predictor of prostate growth than prostate volume [58]. In addition, the PLESS study showed that PSA also predicted the changes in symptoms, QoL/bother, and maximum flow-rate (Q_{max}) [59]. In a longitudinal study of men managed conservatively, PSA was a highly significant predictor of clinical progression [60, 61]. In the placebo arms of large double-blind studies, baseline serum PSA predicted the risk of acute urinary retention (AUR) and BPE-related surgery [62, 63]. An equivalent link was also confirmed by the Olmsted County Study. The risk for treatment was higher in men with a baseline PSA of > 1.4 ng/mL [64]. Patients with BPO seem to have a higher PSA level and larger prostate volumes. The positive predictive value (PPV) of PSA for the detection of BPO was recently shown to be 68% [65]. Furthermore, in an epidemiological study, elevated free PSA levels could predict clinical BPH, independent of total PSA levels [66].

Summary of evidence	LE
Prostate-specific antigen has a good predictive value for assessing prostate volume and is a strong predictor of prostate growth.	1b
Baseline PSA can predict the risk of AUR and BPE-related surgery.	1b

Recommendations	Strength rating
Measure prostate-specific antigen (PSA) if a diagnosis of prostate cancer will change management.	Strong
Measure PSA if it assists in the treatment and/or decision making process.	Strong

4.7 Renal function measurement

Renal function may be assessed by serum creatinine or estimated glomerular filtration rate (eGFR). Hydronephrosis, renal insufficiency or urinary retention are more prevalent in patients with signs or symptoms of BPO [67]. Even though BPO may be responsible for these complications, there is no conclusive evidence on the mechanism [68].

One study reported that 11% of men with LUTS had renal insufficiency [67]. Neither symptom score nor QoL was associated with the serum creatinine level. Diabetes mellitus or hypertension were the most likely causes of the elevated creatinine concentration. Comiter *et al*. [69] reported that non-neurogenic voiding dysfunction is not a risk factor for elevated creatinine levels. Koch *et al.* [70] concluded that only those with an elevated creatinine level require investigational ultrasound (US) of the kidney.

In the Olmsted County study community-dwelling men there was a cross-sectional association between signs and symptoms of BPO (though not prostate volume) and chronic kidney disease (CKD) [71]. In 2,741 consecutive patients who presented with LUTS, decreased Q_{max}, a history of hypertension and/or diabetes were associated with CKD [72]. Another study demonstrated a correlation between Q_{max} and eGFR in middle-aged men with moderate-to-severe LUTS [73]. Patients with renal insufficiency are at an increased risk of developing post-operative complications [74].

Summary of evidence	LE
Decreased Q_{max} and a history of hypertension and/or diabetes are associated with CKD in patients who present with LUTS.	3
Patients with renal insufficiency are at an increased risk of developing post-operative complications.	3

Recommendation	Strength rating
Assess renal function if renal impairment is suspected based on history and clinical examination, or in the presence of hydronephrosis, or when considering surgical treatment for male LUTS.	Strong

4.8 Post-void residual urine

Post-void residual (PVR) urine can be assessed by transabdominal US, bladder scan or catheterisation. Post-void residual is not necessarily associated with BOO, since high PVR volumes can be a consequence of obstruction and/or poor detrusor function (detrusor underactivity [DUA]) [75, 76]. Using a PVR threshold of 50 mL, the diagnostic accuracy of PVR measurement has a PPV of 63% and a negative predictive value (NPV) of 52% for the prediction of BOO [77]. A large PVR is not a contraindication to watchful waiting (WW) or medical therapy, although it may indicate a poor response to treatment and especially to WW. In both the MTOPS and ALTESS studies, a high baseline PVR was associated with an increased risk of symptom progression [62, 63].

Monitoring of changes in PVR over time may allow for identification of patients at risk of AUR [63]. This is of particular importance for the treatment of patients using antimuscarinic medication. In contrast, baseline PVR has little prognostic value for the risk of BPE-related invasive therapy in patients on α1-blockers or WW [78]. However, due to large test-retest variability and lack of outcome studies, no PVR threshold for treatment decision has yet been established; this is a research priority.

Summary of evidence	LE
The diagnostic accuracy of PVR measurement, using a PVR threshold of 50 mL, has a PPV of 63% and a NPV of 52% for the prediction of BOO.	3
Monitoring of changes in PVR over time may allow for identification of patients at risk of AUR.	3

Recommendation	Strength rating
Measure post-void residual in the assessment of male LUTS.	Weak

4.9 Uroflowmetry

Urinary flow rate assessment is a widely used non-invasive urodynamic test. Key parameters are Q_{max} and flow pattern. Uroflowmetry parameters should preferably be evaluated with voided volume > 150 mL. As Q_{max} is prone to within-subject variation [79, 80], it is useful to repeat uroflowmetry measurements, especially if the voided volume is < 150 mL, or Q_{max} or flow pattern is abnormal.

The diagnostic accuracy of uroflowmetry for detecting BOO varies considerably and is substantially influenced by threshold values. A threshold Q_{max} of 10 mL/s has a specificity of 70%, a PPV of 70% and a sensitivity of 47% for BOO. The specificity using a threshold Q_{max} of 15 mL/s was 38%, the PPV 67% and the sensitivity 82% [81]. If Q_{max} is > 15 mL/s, physiological compensatory processes mean that BOO cannot be excluded. Low Q_{max} can arise as a consequence of BOO [82], DUA or an under-filled bladder [83]. Therefore, it is limited as a diagnostic test as it is unable to discriminate between the underlying mechanisms. Specificity can be improved by repeated flow rate testing. Uroflowmetry can be used for monitoring treatment outcomes [84] and correlating symptoms with objective findings.

Summary of evidence	LE
The diagnostic accuracy of uroflowmetry for detecting BOO varies considerably and is substantially influenced by threshold values. Specificity can be improved by repeated flow rate testing.	2b
Monitoring of changes in PVR over time may allow for identification of patients at risk of AUR.	3

Recommendations	Strength rating
Perform uroflowmetry in the initial assessment of male LUTS.	Weak
Perform uroflowmetry prior to medical or invasive treatment.	Strong

4.10 Imaging

*4.10.1 **Upper urinary tract***

Men with LUTS are not at increased risk for upper tract malignancy or other abnormalities when compared to the overall population [70, 85-87]. Several arguments support the use of renal US in preference to intravenous urography. Ultrasound allows for better characterisation of renal masses, the possibility of investigating the liver and retroperitoneum, and simultaneous evaluation of the bladder, PVR and prostate, together with a lower cost, radiation dose and less side effects [85]. Ultrasound can be used for the evaluation of men with large PVR, haematuria, or a history of urolithiasis.

Summary of evidence	LE
Men with LUTS are not at increased risk for upper tract malignancy or other abnormalities when compared to the overall population.	3
Ultrasound can be used for the evaluation of men with large PVR, haematuria, or a history of urolithiasis.	4

Recommendation	Strength rating
Perform ultrasound of the upper urinary tract in men with LUTS.	Weak

*4.10.2 **Prostate***

Imaging of the prostate can be performed by transabdominal US, TRUS, computed tomography (CT), and magnetic resonance imaging (MRI). However, in daily practice, prostate imaging is performed by transabdominal (suprapubic) US or TRUS [85].

4.10.2.1 Prostate size and shape

Assessment of prostate size is important for the selection of interventional treatment, i.e. open prostatectomy (OP), enucleation techniques, transurethral resection, transurethral incision of the prostate (TUIP), or minimally invasive therapies. It is also important prior to treatment with 5α-reductase inhibitors (5-ARIs). Prostate volume predicts symptom progression and the risk of complications [87].

Transrectal US is superior to transabdominal volume measurement [88, 89]. The presence of a median lobe may guide treatment choice in patients scheduled for a minimally invasive approach since medial lobe presence can be a contraindication for some minimally invasive treatments (see section 5.3).

Summary of evidence	LE
Assessment of prostate size by TRUS or transabdominal US is important for the selection of interventional treatment and prior to treatment with 5-ARIs.	3

Recommendations	Strength rating
Perform imaging of the prostate when considering medical treatment for male LUTS, if it assists in the choice of the appropriate drug.	Weak
Perform imaging of the prostate when considering surgical treatment.	Strong

*4.10.3 **Voiding cysto-urethrogram***

Voiding cysto-urethrogram (VCUG) is not recommended in the routine diagnostic work-up of men with LUTS, but it may be useful for the detection of vesico-ureteral reflux, bladder diverticula, or urethral pathologies. Retrograde urethrography may additionally be useful for the evaluation of suspected urethral strictures.

4.11 Urethrocystoscopy

Patients with a history of microscopic or gross haematuria, urethral stricture, or bladder cancer, who present with LUTS, should undergo urethrocystoscopy during diagnostic evaluation.

A prospective study evaluated 122 patients with LUTS using uroflowmetry and urethrocystoscopy [90]. The pre-operative Q_{max} was normal in 25% of 60 patients who had no bladder trabeculation, 21% of 73 patients with mild trabeculation and 12% of 40 patients with marked trabeculation on cystoscopy. All 21 patients who presented with diverticula had a reduced Q_{max}.

Another study showed that there was no significant correlation between the degree of bladder trabeculation (graded from I to IV), and the pre-operative Q_{max} value in 39 symptomatic men aged 53-83 years [91]. The largest study published on this issue examined the relation of urethroscopic findings to urodynamic studies in 492 elderly men with LUTS [92]. The authors noted a correlation between cystoscopic appearance

(grade of bladder trabeculation and urethral occlusion) and urodynamic indices, DO and low compliance. It should be noted, however, that BOO was present in 15% of patients with normal cystoscopic findings, while 8% of patients had no obstruction, even in the presence of severe trabeculation [92].

Summary of evidence	LE
Patients with a history of microscopic or gross haematuria, urethral stricture, or bladder cancer, who present with LUTS, should undergo urethrocystoscopy during diagnostic evaluation.	3
None of the studies identified a strong association between the urethrocystoscopic and urodynamic findings.	3

Recommendation	Strength rating
Perform urethrocystoscopy in men with LUTS prior to minimally invasive/surgical therapies if the findings may change treatment.	Weak

4.12 Urodynamics

In male LUTS, the most widespread invasive urodynamic techniques employed are filling cystometry and pressure flow studies (PFS). The major goal of urodynamics is to explore the functional mechanisms of LUTS, to identify risk factors for adverse outcomes and to provide information for shared decision-making. Most terms and conditions (e.g. DO, low compliance, BOO/BPO, DUA) are defined by urodynamic investigation.

4.12.1 Diagnosing bladder outlet obstruction

Pressure flow studies are the basis for the definition of BOO, which is characterised by increased detrusor pressure and decreased urinary flow rate during voiding. Bladder outlet obstruction/BPO has to be differentiated from DUA, which exhibits decreased detrusor pressure during voiding in combination with decreased urinary flow rate [5].

Urodynamic testing may also identify DO. Studies have described an association between BOO and DO [93, 94]. In men with LUTS attributed to BPE, DO was present in 61% and independently associated with BOO grade and ageing [93].

The prevalence of DUA in men with LUTS is 11-40% [95, 96]. Detrusor contractility does not appear to decline in long-term BOO and surgical relief of BOO does not improve contractility [97, 98]. There are no published RCTs in men with LUTS and possible BPO that compare the standard practice investigation (uroflowmetry and PVR measurement) with PFS with respect to the outcome of treatment; however, a study has been completed in the UK, but the final results have not yet been published [99, 100].

A Cochrane meta-analysis was done to determine whether performing invasive urodynamic investigation reduces the number of men with continuing symptoms of voiding dysfunction. Two trials with 350 patients were included. Invasive urodynamic testing changed clinical decision making. Patients who underwent urodynamics were less likely to undergo surgery; however, no evidence was found to demonstrate whether this led to reduced symptoms of voiding dysfunction after treatment [101]. A more recent meta-analysis of retrospective studies showed that pre-operative urodynamic DOA has no diagnostic role in the prediction of surgical outcomes in patients with male BOO [102].

Due to the invasive nature of the test, a urodynamic investigation is generally only offered if conservative treatment has failed. The Guidelines Panel attempted to identify specific indications for PFS based on age, findings from other diagnostic tests and previous treatments. The Panel allocated a different degree of obligation for PFS in men > 80 years and men < 50 years, which reflects the lack of evidence. In addition, there was no consensus whether PFS should or may be performed when considering surgery in men with bothersome predominantly voiding LUTS and Q_{max} > 10 mL/s, although the Panel recognised that with a Q_{max} < 10 mL/s, BOO is likely and PFS is not necessarily needed.

Patients with neurological disease, including those with previous radical pelvic surgery, should be assessed according to the EAU Guidelines on Neuro-Urology [103].

4.12.2 Videourodynamics

Videourodynamics provides additional anatomical and functional information and may be recommended if the clinician considers this is needed to understand the pathophysiological mechanism of an individual patient's LUTS.

Summary of evidence	LE
There are no RCTs in men with LUTS and possible BPO that compare the standard practice investigation (uroflowmetry and PVR measurement) with PFS with respect to the outcome of treatment.	3

Recommendations	Strength rating
Perform pressure-flow studies (PFS) only in individual patients for specific indications prior to invasive treatment or when evaluation of the underlying pathophysiology of LUTS is warranted.	Weak
Perform PFS in men who have had previous unsuccessful (invasive) treatment for LUTS.	Weak
Perform PFS in men considering invasive treatment who cannot void > 150 mL.	Weak
Perform PFS when considering surgery in men with bothersome predominantly voiding LUTS and Q_{max} > 10 mL/s.	Weak
Perform PFS when considering invasive therapy in men with bothersome, predominantly voiding LUTS with a post void residual > 300 mL.	Weak
Perform PFS when considering invasive treatment in men with bothersome, predominantly voiding LUTS aged > 80 years.	Weak
Perform PFS when considering invasive treatment in men with bothersome, predominantly voiding LUTS aged < 50 years.	Weak

4.13 Non-invasive tests in diagnosing bladder outlet obstruction in men with LUTS

4.13.1 Prostatic configuration/intravesical prostatic protrusion (IPP)

Prostatic configuration can be evaluated with TRUS, using the concept of the presumed circle area ratio (PCAR) [104]. The PCAR evaluates how closely the transverse US image of the prostate approaches a circular shape. The ratio tends toward one as the prostate becomes more circular. The sensitivity of PCAR was 77% for diagnosing BPO when PCAR was > 0.8, with 75% specificity [104].

Ultrasound measurement of IPP assesses the distance between the tip of the prostate median lobe and bladder neck in the midsagittal plane, using a suprapubically positioned US scanner, with a bladder volume of 150-250 mL; grade I protrusion is 0-4.9 mm, grade II is 5-10 mm and grade III is > 10 mm.

Intravesical prostatic protrusion correlates well with BPO (presence and severity) on urodynamic testing, with a PPV of 94% and a NPV of 79% [105]. Intravesical prostatic protrusion may also correlate with prostate volume, DO, bladder compliance, detrusor pressure at maximum urinary flow, BOO index and PVR, and negatively correlates with Q_{max} [106]. Furthermore, IPP also appears to successfully predict the outcome of a trial without catheter after AUR [107, 108]. However, no information with regard to intra- or inter-observer variability and learning curve is yet available. Therefore, whilst IPP may be a feasible option to infer BPO in men with LUTS, the role of IPP as a non-invasive alternative to PFS in the assessment of male LUTS remains under evaluation.

4.13.2 Bladder/detrusor wall thickness and ultrasound-estimated bladder weight

For bladder wall thickness (BWT) assessment, the distance between the mucosa and the adventitia is measured. For detrusor wall thickness (DWT) assessment, the only measurement needed is the detrusor sandwiched between the mucosa and adventitia [109].

A correlation between BWT and PFS parameters has been reported. A threshold value of 5 mm at the anterior bladder wall with a bladder filling of 150 mL was best at differentiating between patients with or without BOO [110]. Detrusor wall thickness at the anterior bladder wall with a bladder filling > 250 mL (threshold value for BOO > 2 mm) has a PPV of 94% and a specificity of 95%, achieving 89% agreement with PFS [73]. Threshold values of 2.0, 2.5, or 2.9 mm for DWT in patients with LUTS are able to identify 81%, 89%, and 100% of patients with BOO, respectively [111].

All studies found that BWT or DWT measurements have a higher diagnostic accuracy for detecting BOO than Q_{max} or Q_{ave} of free uroflowmetry, measurements of PVR, prostate volume, or symptom severity. One study could not demonstrate any difference in BWT between patients with normal urodynamics, BOO or DO. However, the study did not use a specific bladder filling volume for measuring BWT [112]. Disadvantages of the method include the lack of standardisation, and lack of evidence to indicate which measurement (BWT/DWT) is preferable [113]. Measurement of BWT/DWT is therefore not recommended for the diagnostic work-up of men with LUTS.

Ultrasound-estimated bladder weight (UEBW) may identify BOO with a diagnostic accuracy of 86% at a cut-off value of 35 g [114, 115]. Severe LUTS and a high UEBW (> 35 g) are risk factors for prostate/BPH surgery in men on α-blockers [116].

4.13.3 Non-invasive pressure-flow testing

The penile cuff method, in which flow is interrupted to estimate isovolumetric bladder pressure, shows promising data, with good test repeatability [117] and inter-observer agreement [118]. A nomogram has also been derived [119] whilst a method in which flow is not interrupted is also under investigation [120].

The data generated with the external condom method [121] correlates with invasive PFS in a high proportion of patients [122]. Resistive index [123] and prostatic urethral angle [124] have also been proposed, but are still experimental.

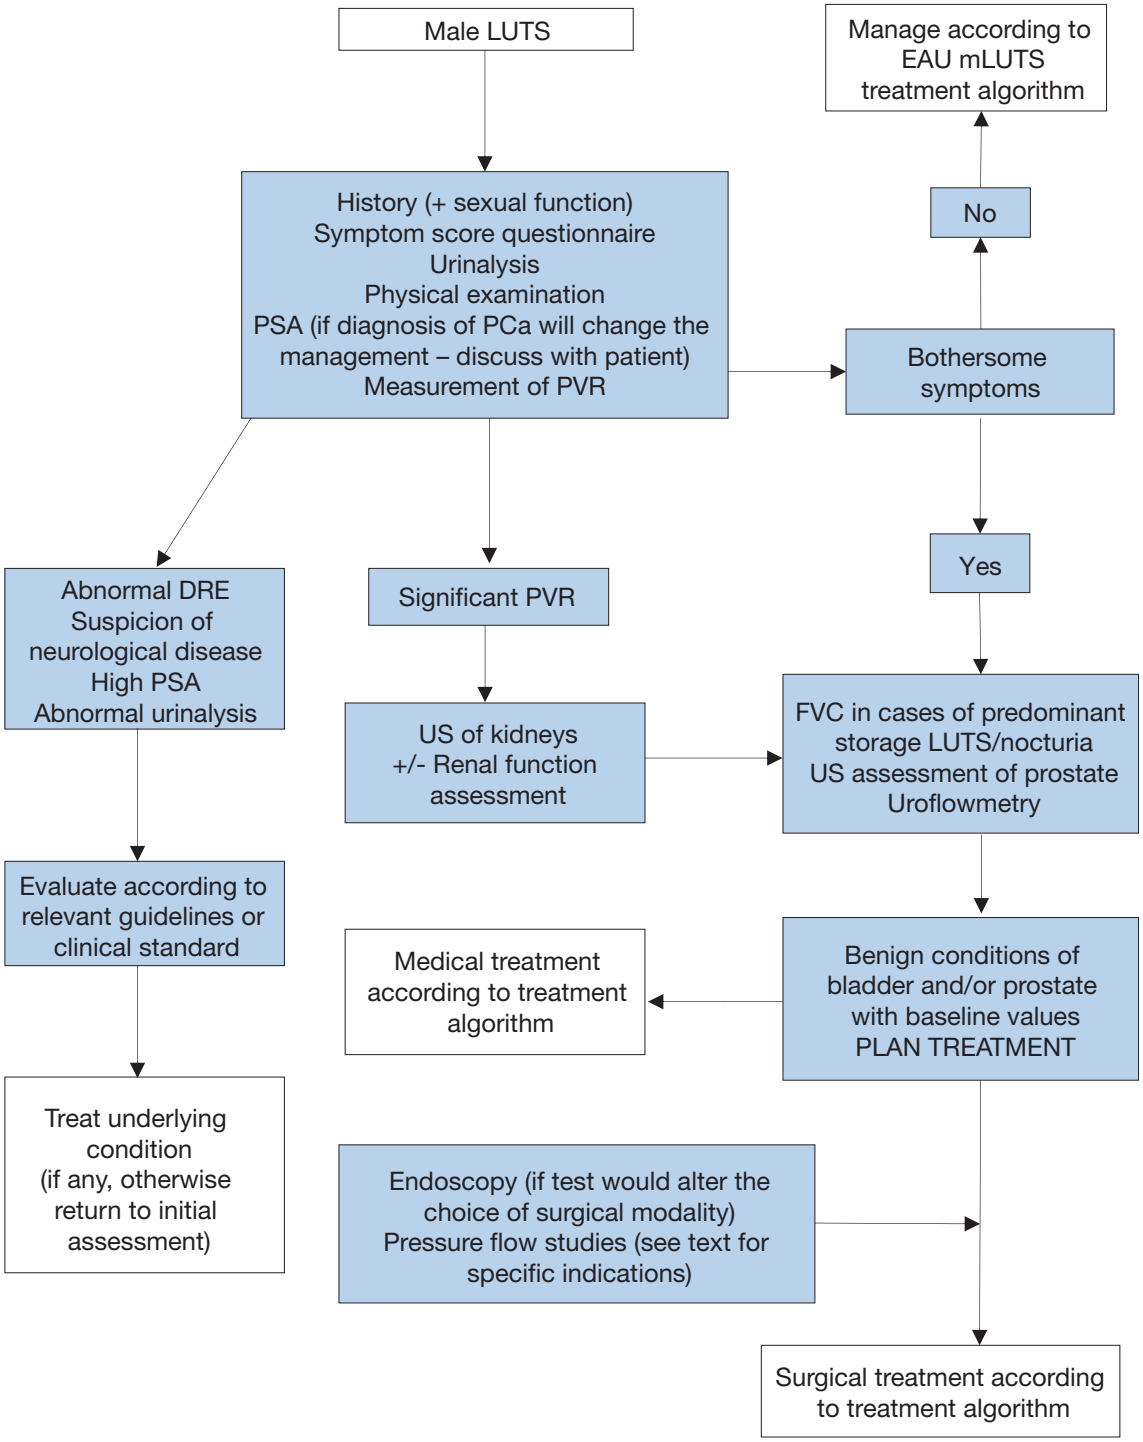
4.13.4 The diagnostic performance of non-invasive tests in diagnosing bladder outlet obstruction in men with LUTS compared with pressure-flow studies

The diagnostic performance of non-invasive tests in diagnosing BOO in men with LUTS compared with PFS has been investigated in a SR [125]. A total of 42 studies were included is this review. The majority were prospective cohort studies, and the diagnostic accuracy of the following non-invasive tests were assessed: penile cuff test; uroflowmetry; detrusor/bladder wall thickness; bladder weight; external condom catheter method; IPP; Doppler US; prostate volume/height; near-infrared spectroscopy. Overall, although the majority of studies have a low risk of bias, data regarding the diagnostic accuracy of these non-invasive tests is limited by the heterogeneity of the studies in terms of the threshold values used to define BOO, the different urodynamic definitions of BOO used across different studies and the small number of studies for each test. It was found that specificity, sensitivity, PPV and NPV of the non-invasive tests were highly variable. Therefore, even though several tests have shown promising results regarding non-invasive diagnosis of BOO, invasive urodynamics remains the modality of choice.

Summary of evidence	**LE**
Data regarding the diagnostic accuracy of non-invasive tests is limited by the heterogeneity of the studies as well as the small number of studies for each test.	1a
Specificity, sensitivity, PPV and NPV of the non-invasive tests were highly variable.	1a

Recommendation	**Strength rating**
Do not offer non-invasive tests as an alternative to pressure-flow studies for diagnosing bladder outlet obstruction in men.	Strong

Figure 2: Assessment algorithm of LUTS in men aged 40 years or older
Readers are strongly recommended to read the full text that highlights the current position of each test in detail.



DRE = digital-rectal examination; FVC = frequency volume chart; LUTS = lower urinary tract symptoms; PCa = prostate cancer; PSA = prostate specific antigen; PVR = post-void residual; US = ultrasound.

5. DISEASE MANAGEMENT

5.1 Conservative treatment

5.1.1 Watchful waiting (WW)

Many men with LUTS are not troubled enough by their symptoms to need drug treatment or surgical intervention. All men with LUTS should be formally assessed prior to any allocation of treatment in order to establish symptom severity and to differentiate between men with uncomplicated (the majority) and

complicated LUTS. Watchful waiting is a viable option for many men with non-bothersome LUTS as few will progress to AUR and complications (e.g. renal insufficiency or stones) [126, 127], whilst others can remain stable for years [128]. In one study, approximately 85% of men with mild LUTS were stable on WW at one year [129].

A study comparing WW and transurethral resection of the prostate (TURP) in men with moderate LUTS showed the surgical group had improved bladder function (flow rates and PVR volumes), especially in those with high levels of bother; 36% of WW patients crossed over to surgery within five years, leaving 64% doing well in the WW group [130, 131]. Increasing symptom bother and PVR volumes are the strongest predictors of clinical failure. Men with mild-to-moderate uncomplicated LUTS who are not too troubled by their symptoms are suitable for WW.

*5.1.2 **Behavioural and dietary modifications***

It is customary for this type of management to include the following components:

- education (about the patient's condition);
- reassurance (that cancer is not a cause of the urinary symptoms);
- periodic monitoring;
- lifestyle advice [128, 129, 132, 133] such as:
    - reduction of fluid intake at specific times aimed at reducing urinary frequency when most inconvenient (e.g. at night or when going out in public);
    - avoidance/moderation of intake of caffeine or alcohol, which may have a diuretic and irritant effect, thereby increasing fluid output and enhancing frequency, urgency and nocturia;
    - use of relaxed and double-voiding techniques;
    - urethral milking to prevent post-micturition dribble;
    - distraction techniques such as penile squeeze, breathing exercises, perineal pressure, and mental tricks to take the mind off the bladder and toilet, to help control storage symptoms;
    - bladder retraining that encourages men to hold on when they have sensory urgency to increase their bladder capacity and the time between voids;
    - reviewing the medication and optimising the time of administration or substituting drugs for others that have fewer urinary effects (these recommendations apply especially to diuretics);
    - providing necessary assistance when there is impairment of dexterity, mobility or mental state;
    - treatment of constipation.

There now exists evidence that self-management as part of WW reduces both symptoms and progression [132, 133]. Men randomised to three self-management sessions in addition to standard care had better symptom improvement and QoL than men treated with standard care only, for up to a year [132].

*5.1.3 **Practical considerations***

The components of self-management have not been individually studied. The above components of lifestyle advice have been derived from formal consensus methodology [134]. Further research in this area is required.

Summary of evidence	**LE**
Watchful waiting is usually a safe alternative for men who are less bothered by urinary difficulty or who wish to delay treatment. The treatment failure rate over a period of five years was 21%; 79% of patients were clinically stable.	1b
An additional study reported 81% of patients were clinically stable on WW after a mean follow-up of seventeen months.	2
Men randomised to three self-management sessions in addition to standard care had better symptom improvement and QoL than men treated with standard care alone at up to a year. Self-management as part of WW reduces both symptoms and progression.	1b

Recommendations	**Strength rating**
Offer men with mild/moderate symptoms, minimally bothered by their symptoms, watchful waiting.	Strong
Offer men with LUTS lifestyle advice prior to, or concurrent with, treatment.	Strong

5.2 Pharmacological treatment

5.2.1 α*1-Adrenoceptor antagonists (*α*1-blockers)*

Mechanism of action: α1-blockers aim to inhibit the effect of endogenously released noradrenaline on smooth muscle cells in the prostate and thereby reduce prostate tone and BOO [135]. However, α1-blockers have little effect on urodynamically determined bladder outlet resistance [136], and treatment-associated improvement of LUTS correlates poorly with obstruction [137]. Thus, other mechanisms of action may also be relevant.

Alpha-1-adrenoceptors located outside the prostate (e.g. urinary bladder and/or spinal cord) and α1-adrenoceptor subtypes (α1B- or α1D-adrenoceptors) may play a role as mediators of effects. α1-adrenoceptors in blood vessels, other non-prostatic smooth muscle cells, and the central nervous system may mediate adverse events.

Currently available α1-blockers are: alfuzosin hydrochloride (alfuzosin); doxazosin mesylate (doxazosin); silodosin; tamsulosin hydrochloride (tamsulosin); terazosin hydrochloride (terazosin); and naftopidil. Alpha-1-blockers exist in different formulations. Although different formulations result in different pharmacokinetic and tolerability profiles, the overall difference in clinical efficacy between the difference formulations seems modest.

Efficacy: Indirect comparisons and limited direct comparisons between α1-blockers demonstrate that all α1-blockers have a similar efficacy in appropriate doses [138]. Clinical effects take a few weeks to develop fully, but significant efficacy over placebo can occur within hours to days [137].

Controlled studies show that α1-blockers typically reduce IPSS by approximately 30-40% and increase Q_{max} by approximately 20-25%. However, considerable improvements also occurred in the corresponding placebo arms [60, 139]. In open-label studies, an IPSS improvement of up to 50% and Q_{max} increase of up to 40% were documented [60, 139]. A recent SR and meta-analysis suggested that Q_{max} variation underestimates the real effect of α1-blockers on BPO, as small improvements in Q_{max} correspond to relevant improvements in BOO index in PFS [140].

Alpha-1-blockers can reduce both storage and voiding LUTS. Prostate size does not affect α1-blocker efficacy in studies with follow-up periods of less than one year, but α1-blockers do seem to be more efficacious in patients with smaller prostates (< 40 mL) in longer-term studies [62, 141-144]. The efficacy of α1-blockers is similar across age groups [139]. In addition, α1-blockers neither reduce prostate size nor prevent AUR in long-term studies [142-144]; however, recent evidence suggests that the use of a1-blockers (alfuzosin and tamsulosin) may improve resolution of AUR [145]. Nonetheless, IPSS reduction and Q_{max} improvement during α1-blocker treatment appears to be maintained over at least four years.

Tolerability and safety: Tissue distribution, subtype selectivity, and pharmacokinetic profiles of certain formulations may contribute to the tolerability profile of specific drugs. The most frequent adverse events of α1-blockers are asthenia, dizziness and (orthostatic) hypotension. Vasodilating effects are most pronounced with doxazosin and terazosin, and are less common with alfuzosin and tamsulosin [146]. Patients with cardiovascular comorbidity and/or vaso-active co-medication may be susceptible to α1-blocker-induced vasodilatation [147]. In contrast, the frequency of hypotension with the α1A-selective blocker silodosin is comparable with placebo [148]. In a large retrospective cohort analysis of men aged > 66 years treated with α1-blockers the risks of falling (odds ratio [OR] 1.14) and of sustaining a fracture (OR 1.16) was increased, most likely as a result of induced hypotension [149].

An adverse ocular event termed intra-operative floppy iris syndrome (IFIS) was reported in 2005, affecting cataract surgery [150]. A meta-analysis on IFIS after alfuzosin, doxazosin, tamsulosin or terazosin exposure showed an increased risk for all α1-blockers [151]. However, the OR for IFIS was much higher for tamsulosin. It appears prudent not to initiate α1-blocker treatment prior to scheduled cataract surgery, and the ophthalmologist should be informed about α1-blocker use.

A SR concluded that α1-blockers do not adversely affect libido, have a small beneficial effect on erectile function, but can cause abnormal ejaculation [152]. Originally, abnormal ejaculation was thought to be retrograde, but more recent data demonstrate that it is due to a decrease or absence of seminal fluid during ejaculation, with young age being an apparent risk factor. In a recent meta-analysis ejaculatory dysfunction (EjD) was significantly more common with α1-blockers than with placebo (OR 5.88). In particular, EjD was significantly more commonly related with tamsulosin or silodosin (OR: 8.57 and 32.5) than placebo, while both doxazosin and terazosin (OR 0.80 and 1.78) were associated with a low risk of EjD [153]. In the meta-regression, the occurrence of EjD was independently associated with the improvement of urinary symptoms and flow rate, suggesting that the more effective the α1-blocker is the greater the incidence of EjD.

Practical considerations: α1-blockers are usually considered the first-line drug treatment for male LUTS because of their rapid onset of action, good efficacy, and low rate and severity of adverse events. However, α1-blockers do not prevent occurrence of urinary retention or need for surgery. Ophthalmologists should be informed about α1-blocker use prior to cataract surgery. Elderly patients treated with non-selective α1-blockers should be informed about the risk of orthostatic hypotension. Sexually active patients treated with selective α1-blockers should be counselled about the risk of EjD.

Summary of evidence	LE
α1-blockers are effective in reducing urinary symptoms (IPSS) and increasing the peak urinary flow rate (Q_{max}) compared with placebo.	1a
Alfuzosin, terazosin and doxazosin showed a statistically significant increased risk of developing vascular-related events compared with placebo.	1a
Alfuzosin, doxazosin, tamsulosin or terazosin exposure has been associated with an increased risk of IFIS.	1a
Ejaculatory dysfunction is significantly more common with α1-blockers than with placebo, particularly with more selective α1-blockers such as tamsulosin and silodosin.	1a

Recommendation	Strength rating
Offer α1-blockers to men with moderate-to-severe LUTS.	Strong

*5.2.2 **5α-reductase inhibitors***

Mechanism of action: Androgen effects on the prostate are mediated by dihydrotestosterone (DHT), which is converted from testosterone by the enzyme 5α-reductase [154], which has two isoforms:

- 5α-reductase type 1: predominant expression and activity in the skin and liver.
- 5α-reductase type 2: predominant expression and activity in the prostate.

Two 5-ARIs are available for clinical use: dutasteride and finasteride. Finasteride inhibits only 5α-reductase type 2, whereas dutasteride inhibits both 5α-reductase types (dual 5-ARI). 5α-reductase inhibitors induce apoptosis of prostate epithelial cells [155] leading to prostate size reduction of about 18-28% and a decrease in circulating PSA levels of about 50% after six to twelve months of treatment [156]. Mean prostate volume and PSA reduction may be even more pronounced after long-term treatment. Continuous treatment reduces the serum DHT concentration by approximately 70% with finasteride and 95% with dutasteride. However, prostate DHT concentration is reduced to a similar level (85-90%) by both 5-ARIs.

Efficacy: Clinical effects relative to placebo are seen after treatment of at least six months. After two to four years of treatment 5-ARIs improve IPSS by approximately 15-30%, decrease prostate volume by 18-28%, and increase Q_{max} by 1.5-2.0 mL/s in patients with LUTS due to prostate enlargement [62, 143, 144, 157-163]. An indirect comparison and one direct comparative trial (twelve months duration) indicate that dutasteride and finasteride are equally effective in the treatment of LUTS [156, 164]. Symptom reduction depends on initial prostate size.

Finasteride may not be more efficacious than placebo in patients with prostates < 40 mL [165]. However, dutasteride seems to reduce IPSS, prostate volume, and the risk of AUR, and to increase Q_{max} even in patients with prostate volumes of between 30 and 40 mL [166, 167]. A long-term trial with dutasteride in symptomatic men with prostate volumes > 30 mL and increased risk for disease progression showed that dutasteride reduced LUTS at least as much as the α1-blocker tamsulosin [143, 163, 168]. The greater the baseline prostate volume (or serum PSA level), the faster and more pronounced the symptomatic benefit of dutasteride as compared to tamsulosin.

5α-reductase inhibitors, but not α1-blockers, reduce the long-term (> 1 year) risk of AUR or need for surgery [62, 161, 169]. In the PLESS study, finasteride reduced the relative risk of AUR by 57% and need for surgery by 55% (absolute risk reduction 4% and 7%, respectively) at four years, compared with placebo [161]. In the MTOPS study, finasteride reduced the relative risk of AUR by 68% and need for surgery by 64% (absolute risk reduction 2% and 3%, respectively), also at four years [62]. A pooled analysis of three randomised trials with two-year follow-up data, reported that treatment with finasteride decreased the relative risk of AUR by 57%, and surgical intervention by 34% (absolute risk reduction 2% for both) in patients with moderately symptomatic LUTS [170]. Dutasteride has also demonstrated efficacy in reducing the risks for AUR and BPH-related surgery. Open-label trials have demonstrated relevant changes in urodynamic parameters [171, 172]. Furthermore, finasteride might reduce blood loss during transurethral prostate surgery, probably due to its effects on prostatic vascularisation [173, 174].

Tolerability and safety: The most common adverse events are reduced libido, erectile dysfunction (ED) and less frequently, ejaculation disorders such as retrograde ejaculation, ejaculation failure, or decreased semen volume [62, 144, 156, 175]. Gynaecomastia (with breast or nipple tenderness) develops in 1-2% of patients. Two studies have suggested that treatment with 5-ARIs is associated with a higher incidence of high-grade cancers although no causal relationship has been proven [176, 177]. There is a long-standing debate regarding potential cardiovascular side effects of 5-ARIs, in particular dutasteride [178]. Population-based studies in Taiwan and Ontario did not find an association between the use of 5-ARIs and increased cardiovascular side effects [178, 179].

Practical considerations: Treatment with 5-ARIs should be considered in men with moderate-to-severe LUTS and an enlarged prostate (> 40 mL) and/or elevated PSA concentration (> 1.4-1.6 ng/mL). They can prevent the risk of AUR and need for surgery. Due to the slow onset of action, they are not suitable for short-term use. Their effect on PSA needs to be considered in relation to PCa screening.

Summary of evidence	**LE**
After two to four years of treatment, 5-ARIs improve IPSS by approximately 15-30%, decrease prostate volume by 18-28%, and increase Q_{max} by 1.5-2.0 mL/s in patients with LUTS due to prostate enlargement.	1b
5α-reductase inhibitors can prevent disease progression with regard to AUR and the need for surgery. Due to their slow onset of action, they are suitable only for long-term treatment (years).	1a
The most relevant adverse effects of 5-ARIs are related to sexual function, and include reduced libido, ED and less frequently, ejaculation disorders such as retrograde ejaculation, ejaculation failure, or decreased semen volume.	1b

Recommendations	**Strength rating**
Use 5α-reductase inhibitors in men who have moderate-to-severe LUTS and an increased risk of disease progression (e.g. prostate volume > 40 mL).	Strong
Counsel patients about the onset of action (three to six months) of 5α-reductase inhibitors.	Strong

*5.2.3 **Muscarinic receptor antagonists***

Mechanism of action: The detrusor is innervated by parasympathetic nerves whose main neurotransmitter is acetylcholine, which stimulates muscarinic receptors (M-cholinoreceptors) on the smooth muscle cells. Muscarinic receptors are also present on other cell types, such as bladder urothelial cells and epithelial cells of the salivary glands. Five muscarinic receptor subtypes (M1-M5) have been described, of which M2 and M3 are predominant in the detrusor. The M2 subtype is more numerous, but the M3 subtype is functionally more important in bladder contractions [180, 181]. Antimuscarinic effects might also be induced or modulated through other cell types, such as the bladder urothelium or by the central nervous system [182, 183].

The following muscarinic receptor antagonists are licensed for treating OAB/storage symptoms: darifenacin hydrobromide (darifenacin); fesoterodine fumarate (fesoterodine); oxybutynin hydrochloride (oxybutynin); propiverine hydrochloride (propiverine); solifenacin succinate (solifenacin); tolterodine tartrate (tolterodine); and trospium chloride. Transdermal preparations of oxybutynin have been formulated and evaluated in clinical trials [184, 185].

Efficacy: Antimuscarinics were mainly tested in females in the past, as it was believed that LUTS in men were caused by the prostate, so should be treated with prostate-specific drugs. However, there is no scientific data for this assumption [186]. A sub-analysis of an open-label trial of OAB patients showed that age but not gender had an impact on urgency, frequency, or urgency incontinence [187]. In a pooled analysis, which included a sub-analysis of male patients, fesoterodine 8 mg was superior to tolterodine extended release (ER) 4 mg for the improvement of severe urgency episodes/24 hours and the OAB-q Symptom Bother score at week twelve, the urinary retention rate was around 2% [188].

The efficacy of antimuscarinics as single agents in men with OAB in the absence of BOO have been tested [189-194]. Most trials lasted only twelve weeks. Four *post hoc* analyses of large RCTs on the treatment of OAB in women and men without presumed BOO were performed focusing only on the men [186, 190, 195]. Tolterodine can significantly reduce urgency incontinence, daytime or 24-hour frequency and urgency-related voiding whilst improving patient perception of treatment benefit. Solifenacin significantly improved mean patient perception of bladder condition scores, mean OAB questionnaire scores, and overall perception of

bladder problems. Fesoterodine improved micturition frequency, urgency episodes, and urgency urinary incontinence (UUI) episodes. In open-label trials with tolterodine, daytime frequency, nocturia, UUI, and IPSS were significantly reduced compared with baseline values after 12-25 weeks [191, 194]. The TIMES RCT reported that tolterodine ER monotherapy significantly improved UUI episodes per 24 hours compared to placebo, at week twelve. Tolterodine ER did not significantly improve urgency, IPSS total or QoL score compared with placebo. A significantly greater proportion of patients in the tolterodine ER plus tamsulosin group reported treatment benefit compared with the other three treatment groups [193].

A further analysis showed that men with PSA levels of < 1.3 ng/mL (smaller prostates) might benefit more from antimuscarinics [196]. Two other studies found a positive effect of antimuscarinics in patients with OAB and concomitant BPO [194, 197]. In a small RCT propiverine improved frequency and urgency episodes [197].

Tolerability and safety: Antimuscarinic drug trials generally show approximately 3-10% withdrawals, which is similar to placebo. Drug-related adverse events include dry mouth (up to 16%), constipation (up to 4%), micturition difficulties (up to 2%), nasopharyngitis (up to 3%), and dizziness (up to 5%).

Increased PVR in men without BOO is minimal and similar to placebo. Nevertheless, fesoterodine 8 mg showed higher PVRs (+20.2 mL) than placebo (-0.6 mL) or fesoterodine 4 mg (+9.6 mL) [191]. Incidence of urinary retention in men without BOO was similar to placebo for tolterodine (0-1.3% vs. 0-1.4%). With fesoterodine 8 mg, 5.3% had symptoms, which was higher than placebo or fesoterodine 4 mg (both 0.8%). These symptoms appeared during the first two weeks of treatment and mainly affected men aged 66 years or older.

Theoretically antimuscarinics might decrease bladder strength, and hence might be associated with PVR urine or urinary retention. A twelve week safety study on men with mild-to-moderate BOO showed that tolterodine increased the PVR (49 mL vs. 16 mL) but not AUR (3% in both arms) [198]. The urodynamic effects included larger bladder volumes at first detrusor contraction, higher maximum cystometric capacity, and decreased bladder contractility index, Q_{max} was unchanged. This trial indicated that short-term treatment with antimuscarinics in men with BOO is safe [192].

Practical considerations: Not all antimuscarinics have been tested in elderly men, and long-term studies on the efficacy of muscarinic receptor antagonists in men of any age with LUTS are not yet available. In addition, only patients with low PVR volumes at baseline were included in the studies. These drugs should therefore be prescribed with caution, and regular re-evaluation of IPSS and PVR urine is advised. Men should be advised to discontinue medication if worsening voiding LUTS or urinary stream is noted after initiation of therapy.

Summary of evidence	**LE**
Antimuscarinic monotherapy can significantly improve urgency, UUI, and increased daytime frequency.	2
Antimuscarinic monotherapy can be associated with increased PVR after therapy, but acute retention is a rare event in men with a PVR volume of < 150 mL at baseline.	2

Recommendations	**Strength rating**
Use muscarinic receptor antagonists in men with moderate-to-severe LUTS who mainly have bladder storage symptoms.	Strong
Do not use antimuscarinic overactive bladder medications in men with a post-void residual volume > 150 mL.	Weak

*5.2.4 **Phosphodiesterase 5 inhibitors***

Mechanism of action: Phosphodiesterase 5 inhibitors (PDE5Is) increase intracellular cyclic guanosine monophosphate, thus reducing smooth muscle tone of the detrusor, prostate and urethra. Nitric oxide and PDE5Is might also alter reflex pathways in the spinal cord and neurotransmission in the urethra, prostate, or bladder [199]. Moreover, chronic treatment with PDE5Is seems to increase blood perfusion and oxygenation in the LUT [200]. Phosphodiesterase 5 inhibitors could also reduce chronic inflammation in the prostate and bladder [201]. The exact mechanism of PDE5Is on LUTS remains unclear.

Although clinical trials of several selective oral PDE5Is have been conducted in men with LUTS, only tadalafil (5 mg once daily) has been licensed for the treatment of male LUTS.

Efficacy: Several RCTs have demonstrated that PDE5Is reduce IPSS, storage and voiding LUTS, and improve QoL. However, Q_{max} did not significantly differ from placebo in most trials.

A recent Cochrane review included a total of sixteen randomised trials that examined the effects

of PDE5Is compared to placebo and other standard of care drugs (α1-blockers and 5-ARIs) in men with LUTS [202]. Phosphodiesterase 5 inhibitors led to a small reduction (mean difference (MD) 1.89 lower, 95% CI 2.27 lower to 1.50 lower) in IPSS compared to placebo. There was no difference between PDE5Is and α1-blockers in IPSS. Most evidence was limited to short-term treatment up to twelve weeks and of moderate or low certainty. In earlier [203] and more recent [204] meta-analysis, PDE5Is were also found to improve IPSS and IIEF score, but not Q_{max}.

Tadalafil 5 mg reduces IPSS by 22-37% and improvement may be seen within a week of initiation of treatment [205]. A three point or greater total IPSS improvement was observed in 60% of tadalafil treated men within one week and in 80% within four weeks [206]. The maximum trial (open label) duration was 52 weeks [207]. A subgroup analysis of pooled data from four RCTs demonstrated a significant reduction in LUTS, regardless of baseline severity, age, previous use of α-blockers or PDE5Is, total testosterone level or predicted prostate volume [208]. In a recent *post hoc* analysis of pooled data from four RCTs, tadalafil was shown to also be effective in men with cardiovascular risk factors/comorbidities, except for patients receiving more than one antihypertensive medication. The use of diuretics may contribute to patients' perception of a negated efficacy [209]. Among sexually active men > 45 years with comorbid LUTS/BPH and ED, tadalafil improved both conditions [208].

An integrated data analyses from four placebo controlled clinical studies showed that total IPSS improvement was largely attributed to direct (92.5%, $p < 0.001$) vs. indirect (7.5%, $p = 0.32$) treatment effects via IIEF-EF improvement [210]. Another analysis showed a small but significant increase in Q_{max} without any effect on PVR [211]. An integrated analysis of RCTs showed that tadalfil was not superior to placebo for IPSS improvement at twelve weeks in men ≥ 75 years (with varied effect size between studies), but was for men < 75 years [212]. An open label urodynamic study of 71 patients showed improvements in both voiding and storage symptoms, confirmed by improvements in BOO index (61.3 to 47.1; $p < 0.001$), and resolution of DO in 15 (38%) of 38 patients. Flow rate improved from 7.1 to 9.1 mL/s ($p < 0.001$) and mean IPSS from 18.2 to 13.4 [213].

A combination of PDE5Is and α-blockers has also been evaluated. A meta-analysis of five RCTs (two studies with tadalafil 20 mg, two with sildenafil 25 mg, and one with vardenafil 20 mg), showed that combination therapy significantly improved IPSS score (-1.8), IIEF score (+3.6) and Q_{max} (+1.5 mL/s) compared with α-blockers alone [203]. A Cochrane review found similar findings [202]. The effects of tadalafil 5 mg combined with finasteride 5 mg were assessed in a 26-week placebo-controlled RCT. The combination of tadalafil and finasteride provided an early improvement in urinary symptoms ($p < 0.022$ after 4, 12 and 26 weeks), with a significant improvement of storage and voiding symptoms and QoL. Combination therapy was well tolerated and improved erectile function [214]. However, only tadalafil 5 mg has been licensed in the context of LUTS management while data on combinations of PDE5Is and other LUTS medications is emerging.

Tolerability and safety: Reported adverse effects in RCTs comparing the effect of all PDE5Is vs. placebo in men with LUTS include flushing, gastroesophageal reflux, headache, dyspepsia, back pain and nasal congestion [203]. The discontinuation rate due to adverse effects for tadalafil was 2.0% [215] and did not differ by age, LUTS severity, testosterone levels, or prostate volume in the pooled data analyses [208].

Phosphodiesterase 5 inhibitors are contraindicated in patients using nitrates, the potassium channel opener nicorandil, or the α1-blockers doxazosin and terazosin. They are also contraindicated in patients who have unstable angina pectoris, have had a recent myocardial infarction (< three months) or stroke (< six months), myocardial insufficiency (New York Heart Association stage > 2), hypotension, poorly controlled blood pressure, significant hepatic or renal insufficiency, or if anterior ischaemic optic neuropathy with sudden loss of vision is known or was reported after previous use of PDE5Is.

Practical considerations: To date, only tadalafil 5 mg once daily has been officially licensed for the treatment of male LUTS with or without ED. The meta-regression suggested that younger men with low body mass index and more severe LUTS benefit the most from treatment with PDE5Is [203]. Long-term experience with tadalafil in men with LUTS is limited to one trial with a one year follow-up [207], therefore conclusions about its efficacy or tolerability greater than one year are not possible. There is limited information on reduction of prostate size and no data on disease progression.

Summary of evidence	**LE**
Phosphodiesterase 5 inhibitors improve IPSS and IIEF score, but not Q_{max}.	1a
A three point or greater total IPSS improvement was observed in 59.8% of tadalafil treated men within one week and in 79.3% within four weeks.	1b

Recommendation	**Strength rating**
Use phosphodiesterase type 5 inhibitors in men with moderate-to-severe LUTS with or without erectile dysfunction.	Strong

5.2.5 *Plant extracts - phytotherapy*

Potential mechanism of action: Herbal drug preparations are made of roots, seeds, pollen, bark, or fruits. There are single plant preparations (mono-preparations) and preparations combining two or more plants in one pill (combination preparations) [216].

Possible relevant compounds include phytosterols, ß-sitosterol, fatty acids, and lectins [216]. *In vitro*, plant extracts can have anti-inflammatory, anti-androgenic and oestrogenic effects; decrease sexual hormone binding globulin; inhibit aromatase, lipoxygenase, growth factor-stimulated proliferation of prostatic cells, α-adrenoceptors, 5 α-reductase, muscarinic cholinoceptors, dihydropyridine receptors and vanilloid receptors; and neutralise free radicals [216-218]. The *in vivo* effects of these compounds are uncertain, and the precise mechanisms of plant extracts remain unclear.

Efficacy: The extracts of the same plant produced by different companies do not necessarily have the same biological or clinical effects; therefore, the effects of one brand cannot be extrapolated to others [219]. In addition, batches from the same producer may contain different concentrations of active ingredients [220]. A review of recent extraction techniques and their impact on the composition/biological activity of available *Serenoa repens* based products showed that results from different clinical trials must be compared strictly according to the same validated extraction technique and/or content of active compounds [221], as the pharmacokinetic properties of the different preparations can vary significantly.

Heterogeneity and a limited regulatory framework characterise the current status of phytotherapeutic agents. The European Medicines Agency (EMA) has developed the Committee on Herbal Medicinal Products (HMPC). European Union (EU) herbal monographs contain the HMPC's scientific opinion on safety and efficacy data about a herbal substances and their preparations intended for medicinal use. The HMPC evaluates all available information, including non-clinical and clinical data, whilst also documenting long-standing use and experience in the EU. European Union monographs are divided into two sections: a) Well established use (marketing authorisation): when an active ingredient of a medicine has been used for more than ten years and its efficacy and safety have been well established (including a review of the relevant literature); and b) Traditional use (simplified registration): for herbal medicinal products which do not fulfil the requirements for a marketing authorisation, but there is sufficient safety data and plausible efficacy on the basis of long-standing use and experience. Table 1 lists the available EU monographs for herbal medicinal products.

Table 2: European Union monographs for herbal medicinal products

Herbal substance	HMPC evaluation	Therapeutic Indication by HMPC	Date of monograph
Serenoa repens, fructus (saw palmetto, fruit) Extraction solvent: hexane [222]	Well established use	Symptomatic treatment of BPH	14/01/2016
Serenoa repens, fructus (saw palmetto, fruit) Extraction solvent: ethanol [222]	Traditional use	LUTS related to BPH*	14/01/2016
Cucurbita pepo L, semen (pumpkin seed) Preparation as defined in the monograph [223]	Traditional use	LUTS related to BPH or related to OAB*	25/03/2013
Prunus africana (Hook f.) Kalkm., cortex (pygeum africanum bark) Preparation as defined in the monograph [224]	Traditional use	LUTS related to BPH*	01/09/2017
Urtica dioica L., Urtica urens L., their hybrids or their mixtures, radix Preparation as defined in the monograph [225]	Traditional use	LUTS related to BPH*	05/11/2012
Epilobium angustifolium L. and/or Epilobium parviflorum Schreb., herba (Willow herb) Preparation as defined in the monograph [226]	Traditional use	LUTS related to BPH*	13/01/2016

**after serious conditions have been excluded by a medical doctor*

Panel interpretation: Only hexane extracted *Serenoa reprens* has been recommended for well-established use by the HMPC. A detailed scoping search covering the timeframe between the search cut-off date of the EU monograph and April 2020 will be conducted for the update of the 2021 edition of the Guidelines. Following this a specific recommendation on phytotherapy will be given.

5.2.6 ***Beta-3 agonist***

Mechanism of action: Beta-3 adrenoceptors are the predominant beta receptors expressed in the smooth muscle cells of the detrusor and their stimulation is thought to induce detrusor relaxation. The mode of action of beta-3 agonists is not fully elucidated [227].

Efficacy: Mirabegron 50 mg is the first clinically available beta-3 agonist with approval for use in adults with OAB. Mirabegron has undergone extensive evaluation in RCTs conducted in Europe, Australia, North America and Japan [228-232]. Mirabegron demonstrated significant efficacy in treating the symptoms of OAB, including micturition frequency, urgency and UUI and also patient perception of treatment benefit. These studies had a predominantly female study population. A meta-analysis of eight RCTS including 10,248 patients (27% male) found that mirabegron treatment resulted in reduced frequency, urgency and UUI rates, as well as an improved voided volume with a statistically significant improvement of nocturia as compared with both placebo and tolterodine [233].

Mirabegron has been evaluated in male patients with OAB in the context of LUTS either associated with or not associated with BPO confirmed by urodynamics [234]. Mirabegron 25 mg daily led to increased satisfaction and improved QoL, but symptoms assessed by validated questionnaires (IPSS and OAB-SS), only improved in non-obstructed patients. Mirabegron as an add-on therapy has been studied in OAB patients with incontinence despite antimuscarinic therapy [235], again in a predominantly female study population. An Asian study with a higher proportion of male subjects (approximately one third) reported superiority over placebo in reducing frequency of micturition, but did not report the results separately for the genders [236].

In a study of more than 1,000 patients of whom approximately 30% were male, combination therapy of mirabegron 25/50 mg and solifenacin 5/10 mg was associated with statistically significant improvements in patient outcomes and health related QoL vs. solifenacin 5 mg and placebo; however, they did not separate out the effects in men and women [237]. In another study, in which 28% patients were male, mirabegron significantly improved patient reported perception of their condition and QoL whether or not patients were incontinent [238]. A phase IV study, with a small proportion of male subjects, reported addition of mirabegron in people with persisting urgency despite solifenacin in a Japanese population [239].

In an RCT evaluating add-on therapy with mirabegron for OAB symptoms remaining after treatment with tamsulosin 0.2 mg daily in men with BPO, combination therapy was associated with greater improvements in OAB symptom score, in the urinary urgency and daytime frequency part and storage subscore of the IPSS, and in the QoL index compared to monotherapy with tamsulosin [240]. A prospective analysis of 50 elderly men showed that mirabegron add-on therapy was effective for patients whose persistent LUTS and OAB symptoms were not controlled with α1-blocker monotherapy, without causing negative effects on voiding function [241].

An RCT compared the efficacy of mirabegron 50 mg or fesoterodine 4 mg add-on therapy to silodosin in LUTS patients with persisting OAB symptoms [242]. At three months, fesoterodine add-on therapy showed a significantly greater improvement then mirabegron add-on therapy in OAB symptom score-total (-2.8 vs.1.5, p = 0.004), IPSS-QoL (-1.5 vs. -1.1, p = 0.04), and OAB symptom score-urgency score (-1.5 vs. -0.9, p = 0.008). Fesoterodine was also superior in alleviating detrusor overactivity (52.6% vs. 28.9%, p = 0.03).

Tolerability and safety: The most common treatment-related adverse events in the mirabegron groups were hypertension, UTI, headache and nasopharyngitis [228-231]. Mirabegron is contraindicated in patients with severe uncontrolled hypertension (systolic blood pressure $\geq$ 180 mmHg or diastolic blood pressure $\geq$ 110 mmHg, or both). Blood pressure should be measured before starting treatment and monitored regularly during treatment. A combination of thirteen clinical studies including 13,396 patients, 25% of whom were male, showed that OAB treatments (anticholinergics or mirabegron) were not associated with an increased risk of hypertension or cardiovascular events compared to placebo [243]. The proportion of patients with dry mouth and constipation in the mirabegron groups was notably lower than reported in RCTs of other OAB agents or of the active control tolterodine [228]. Evaluation of urodynamic parameters in men with combined BOO and OAB concluded that mirabegron did not adversely affect voiding urodynamic parameters compared to placebo in terms of Q_{max}, detrusor pressure at maximum flow and bladder contractility index [244]. The overall change in PVR with mirabegron is small [244].

A small prospective study (mainly focused on males) has shown that mirabegron 25 mg is safe in patients aged 80 years or more with multiple comorbidities [245]. A pooled analysis of three trials each of twelve weeks and a one year trial showed, in patients aged > 65 years, a more favourable tolerability profile for

mirabegron than antimuscarinics [246]. In an eighteen week study of 3,527 patients (23% male), the incidence of adverse events were higher in the combination (solifenacin 5 mg plus mirabegron 25 mg) group (40%) than the mirabegron 25 mg alone group (32%). Events recorded as urinary retention were low (< 1%), but were reported slightly more frequently in the combined group when compared with the monotherapy and placebo groups. The PVR volume was slightly increased in the combined group compared with solifenacin 5 mg, and the mirabegron monotherapy and placebo groups. Combined therapy with solifenacin 5 mg plus mirabegron 25 mg and solifenacin 5 mg plus mirabegron 50 mg provided improvements in efficacy generally consistent with an additive effect [247].

In a retrospective analysis of persistence and adherence in 21,996 patients, of whom 30% were male, the median time to discontinuation was significantly longer for mirabegron (169 days) compared to tolterodine (56 days) and other antimuscarinics (30-78 days) ($p < 0.0001$). There was no statistical difference between men and women [248]. Data on the safety of combination therapy at twelve months are awaited from the SYNERGY II trial.

Practical considerations: Long-term studies on the efficacy and safety of mirabegron in men of any age with LUTS are not yet available. Studies on the use of mirabegron in combination with other pharmacotherapeutic agents for male LUTS are pending. However, pharmacokinetic interaction upon add-on of mirabegron or tamsulosin to existing tamsulosin or mirabegron therapy does not cause clinically relevant changes in safety profiles [249]. Available studies on mirabegron in combination with antimuscarinics in OAB patients had a predominantly female study population, while further trials are still pending.

Summary of evidence	**LE**
Mirabegron improves the symptoms of OAB, including micturition frequency, urgency and UUI.	2
Patients prescribed mirabegron remained on treatment longer than those prescribed antimuscarinics.	3

Recommendation	**Strength rating**
Use beta-3 agonists in men with moderate-to-severe LUTS who mainly have bladder storage symptoms.	Weak

*5.2.7 **Combination therapies***

5.2.7.1 α1-blockers + 5α-reductase inhibitors

Mechanism of action: Combination therapy consists of an α1-blocker (Section 5.2.1) together with a 5-ARI (Section 5.2.2). The α1-blocker exhibits clinical effects within hours or days, whereas the 5-ARI needs several months to develop full clinical efficacy. Finasteride has been tested in clinical trials with alfuzosin, terazosin, doxazosin or terazosin, and dutasteride with tamsulosin.

Efficacy: Several studies have investigated the efficacy of combination therapy against an α1-blocker, 5-ARI or placebo alone. Initial studies with follow-up periods of six to twelve months demonstrated that the α1-blocker was superior to finasteride in symptom reduction, whereas combination therapy of both agents was not superior to α1-blocker monotherapy [158, 159, 250]. In studies with a placebo arm, the α1-blocker was consistently more effective than placebo, but finasteride was not. Data at one year in the MTOPS study showed similar results [62].

Long-term data (four years) from the MTOPS and CombAT studies showed that combination treatment is superior to monotherapy for symptoms and Q_{max}, and superior to α1-blocker alone in reducing the risk of AUR or need for surgery [62, 143, 144].

The CombAT study demonstrated that combination treatment is superior to either monotherapy regarding symptoms and flow rate starting from month nine, and superior to α1-blocker for AUR and the need for surgery after eight months [144]. Thus, the differences in MTOPS may reflect different inclusion and exclusion criteria and baseline patient characteristics.

Discontinuation of the α1-blocker after six to nine months of combination therapy was investigated by an RCT and an open-label multicentre trial [251, 252]. The first trial evaluated the combination of tamsulosin with dutasteride and the impact of tamsulosin discontinuation after six months [251], with almost three quarters of patients reporting no worsening of symptoms. However, patients with severe symptoms (IPSS > 20) at baseline may benefit from longer combination therapy.

A more recent trial evaluated the symptomatic outcome of finasteride monotherapy at three and nine months after discontinuation of nine-month combination therapy [252]. Lower urinary tract symptom improvement after combination therapy was sustained at three months (IPSS difference 1.24) and nine months (IPSS difference 0.4). The limitations of the studies include the short duration of the studies and the short follow-up period after discontinuation.

In both the MTOPS and CombAT studies, combination therapy was superior to monotherapy in preventing clinical progression as defined by an IPSS increase of at least four points, AUR, UTI, incontinence, or an increase in creatinine > 50%. The MTOPS study found that the risk of long-term clinical progression (primarily due to increasing IPSS) was reduced by 66% with combined therapy vs. placebo and to a greater extent than with either finasteride or doxazosin monotherapy (34% and 39%, respectively) [62]. In addition, finasteride (alone or in combination), but not doxazosin alone, significantly reduced both the risks of AUR and the need for BPH related surgery over the four-year study. In the CombAT study, combination therapy reduced the relative risks of AUR by 68%, BPH-related surgery by 71%, and symptom deterioration by 41% compared with tamsulosin, after four years [253]. To prevent one case of urinary retention and/or surgical treatment thirteen patients need to be treated for four years with dutasteride and tamsulosin combination therapy compared to tamsulosin monotherapy while the absolute risk reduction (risk difference) was 7.7%.

The CONDUCT study compared efficacy and safety of a fixed-dose combination of dutasteride and tamsulosin to a WW approach with the potential initiation of tamsulosin (step-up approach) in a two year RCT with a total of 742 patients. In both arms detailed lifestyle advice was given. This fixed-dose combination resulted in a rapid and sustained improvement in men with moderate LUTS at risk of disease progression, the difference in IPSS at 24 months was 5.4 in the active arm and 3.6 in the placebo arm ($p < 0.001$) [254]. Furthermore, tamsulosin plus dutasteride significantly reduced the relative risk of clinical progression (mainly characterised as a worsening in symptoms) by 43.1% when compared with WW, with an absolute risk reduction of 11.3% (number needed to treat [NNT] = 9).

The influence of baseline variables on changes in IPSS after combination therapy with dutasteride plus tamsulosin or either monotherapy was tested based on the four year results of the CombAT study. Combination therapy provided consistent improvement of LUTS over tamsulosin across all analysed baseline variables at 48 months [255].

More recently, a combination of the 5-ARI, finasteride, and tadalafil 5 mg was tested in a large scale RCT against finasteride monotherapy. This study supports the concept of this novel combination therapy and is described in more detail in the chapter on PDE5Is [214].

Tolerability and safety: Adverse events for both drug classes have been reported with combination treatment [62, 143, 144]. The adverse events observed during combination treatment were typical of α1-blockers and 5-ARIs. The frequency of adverse events was significantly higher for combination therapy. The MTOPS study demonstrated that the incidence of treatment related adverse events is higher during the first year of combined treatment between doxazosin and finasteride [256]. A meta-analysis measuring the impact of medical treatments for LUTS/BPH on ejaculatory function, reported that combination therapy with α1-blockers and 5-ARIs resulted in a three-fold increased risk of EjD as compared with each of the monotherapies [153].

Practical considerations: Compared with α1-blockers or 5-ARI monotherapy, combination therapy results in a greater improvement in LUTS and increase in Q_{max} and is superior in prevention of disease progression. However, combination therapy is also associated with a higher rate of adverse events. Combination therapy should therefore be prescribed primarily in men who have moderate-to-severe LUTS and are at risk of disease progression (higher prostate volume, higher PSA concentration, advanced age, higher PVR, lower Q_{max}, etc.). Combination therapy should only be used when long-term treatment (more than twelve months) is intended and patients should be informed about this. Discontinuation of the α1-blocker after six months might be considered in men with moderate LUTS.

Summary of evidence	**LE**
Long-term data (four years) from the MTOPS and CombAT studies showed that combination treatment is superior to monotherapy for symptoms and Q_{max}, and superior to α1-blocker alone in reducing the risk of AUR or need for surgery.	1b
The MTOPS study found that the risk of long-term clinical progression (primarily due to increasing IPSS) was reduced by 66% with combined therapy vs. placebo and to a greater extent than with either finasteride or doxazosin monotherapy.	1b
The CombAT study found that combination therapy reduced the relative risks of AUR by 68%, BPH-related surgery by 71%, and symptom deterioration by 41% compared with tamsulosin, after four years.	1b
Adverse events of both drug classes are seen with combined treatment using α1-blockers and 5-ARIs.	1b

Recommendation	Strength rating
Offer combination treatment with an α1-blocker and a 5α-reductase inhibitor to men with moderate-to-severe LUTS and an increased risk of disease progression (e.g. prostate volume > 40 mL).	Strong

5.2.7.2 α1-blockers + muscarinic receptor antagonists

Mechanism of action: Combination treatment consists of an α1-blocker together with an antimuscarinic aiming to antagonise both α1-adrenoceptors and muscarinic receptors. The possible combinations have not all been tested in clinical trials yet.

Efficacy: Several RCTs and prospective studies investigated combination therapy, lasting four to twelve weeks, either as an initial treatment in men with OAB and presumed BPO or as a sequential treatment for storage symptoms persisting while on an α1-blocker [193, 253, 257-263]. One trial used the α1-blocker naftopidil (not registered in most European countries) with and without antimuscarinics [264]. A high proportion of men with voiding and storage LUTS need to add anticholinergics after α1-blocker monotherapy, particularly those with longer duration of symptoms at presentation, and men with storage symptoms and a small prostate volume [265].

Combination treatment is more efficacious in reducing urgency, UUI, voiding frequency, nocturia, or IPSS compared with α1-blockers or placebo alone, and improves QoL [193, 266]. Symptom improvement is higher regardless of PSA concentration with combination therapy, whereas tolterodine alone improved symptoms mainly in men with a serum PSA of < 1.3 ng/mL [196].

Persistent LUTS during α1-blocker treatment can be reduced by the additional use of an antimuscarinic, [253, 257, 263, 267, 268]. Two SRs of the efficacy and safety of antimuscarinics in men suggested that combination treatment provides significant benefit [269, 270]. In a meta-analysis of sixteen studies with 3,548 patients with BPH/OAB, initial combination treatment of an α1-blocker with anticholinergic medication improvement storage symptoms and QoL compared to α1-blocker monotherapy without causing significant deterioration of voiding function [271]. There was no difference in total IPSS and Q_{max} between the two groups.

Effectiveness of therapy is evident primarily in those men with moderate-to-severe storage LUTS [272]. Long term use of combination therapy has been reported in patients receiving treatment for up to one year, showing symptomatic response is maintained, with a low incidence of AUR [273]. In men with moderate-to-severe storage symptoms, voiding symptoms and PVR < 150 mL, the reduction in symptoms using combination therapy is associated with patient-relevant improvements in health related quality of life compared with placebo and α1-blocker monotherapy [274].

Tolerability and safety: Adverse events of both drug classes are seen with combined treatment using α1-blockers and antimuscarinics. The most common side-effect is dry mouth. Some side-effects (e.g.dry mouth or ejaculation failure) may show increased incidence which cannot simply be explained by summing the incidence with the drugs used separately. Increased PVR may be seen, but is usually not clinically significant, and risk of AUR is low up to one year of treatment [269, 275]. Antimuscarinics do not cause evident deterioration in maximum flow rate used in conjunction with an α1-blocker in men with OAB symptoms [266, 276].

A recent RCT investigated safety in terms of maximum detrusor pressure and Q_{max} for solifenacin (6 mg or 9 mg) with tamsulosin in men with LUTS and BOO compared with placebo [277]. The combination therapy was not inferior to placebo for the primary urodynamic variables; Q_{max} was increased vs. placebo [277].

Practical considerations: Class effects are likely to underlie efficacy and QoL using an α1-blocker and antimuscarinic. Trials used mainly storage symptom endpoints, were of short duration, and included only men with low PVR volumes at baseline. Therefore, measuring PVR is recommended during combination treatment.

Summary of evidence	LE
Combination treatment with α1-blockers and antimuscarinics is effective for improving LUTS-related QoL impairment.	2
Combination treatment with α1-blockers and antimuscarinics is more effective for reducing urgency, UUI, voiding frequency, nocturia, or IPSS compared with α1-blockers or placebo alone.	2
Adverse events of both drug classes are seen with combined treatment using α1-blockers and antimuscarinics.	1
There is a low risk of AUR using α1-blockers and antimuscarinics in men known to have a PVR urine volume of < 150 mL.	2

Recommendations	Strength rating
Use combination treatment of a α1-blocker with a muscarinic receptor antagonist in patients with moderate-to-severe LUTS if relief of storage symptoms has been insufficient with monotherapy with either drug.	Strong
Do not prescribe combination treatment in men with a post-void residual volume > 150 mL.	Weak

Note: All patients should be counselled about pharmacological treatment related adverse events in order to select the most appropriate treatment for each individual patient.

5.3 Surgical treatment

Despite the advent of new technologies, monopolar TURP has remained the cornerstone of LUTS/BPO surgical treatment for more than nine decades. Extensive clinical research for a more effective and safer alternative is often hindered by methodological limitations, including inadequate follow up. Based on Panel consensus, timeframes defining short-, mid- and long-term follow up of patients submitted to surgical treatments are 12, 36 and over 36 months, respectively. Clinicians should inform patients that long-term surgical RCTs are lacking.

5.3.1 Monopolar Transurethral resection of the prostate and transurethral incision of the prostate

Mechanism of action: Monopolar transurethral resection of the prostate (M-TURP) removes tissue from the transition zone of the gland. Transurethral incision of the prostate involves incising the bladder outlet without tissue removal. This technique may replace M-TURP in selected cases, especially in prostate sizes < 30 mL without a middle lobe.

Efficacy: In a meta-analysis of 20 RCTs with a maximum follow-up of five years, M-TURP resulted in a substantial mean Q_{max} improvement (+162%), a significant reduction in IPSS (-70%), QoL score (-69%), and PVR (-77%) [278]. Monopolar-TURP delivers durable outcomes as shown by studies with a follow-up of 8-22 years. There are no similar data on durability for any other surgical treatment for BPO [279]. One study with a mean follow-up of thirteen years reported a significant and sustained decrease in most symptoms and improvement in urodynamic parameters. Failures were associated with DUA rather than re-development of BPO [98]. Data from an Austrian nationwide study of two cohorts totalling 41,059 men submitted to M-TURP showed that the overall retreatment rates (re-TURP, urethrotomy and bladder neck incision) remained unchanged during the last decade (0.9%, 3.7%, 9.5% and 12.7% at three months, one year, five years, and eight years, respectively), and that the respective incidence of re-TURP was 0.8%, 2.4%, 6.1% and 8.3% [280, 281].

A meta-analysis of ten RCTs found similar LUTS improvements and lower but significant improvements in Q_{max} for TUIP [282]. In this meta-analysis, an upper limit of prostate size was reported as an entry criterion for eight studies with five < 30 mL and three < 60 mL.

A second prostatic operation, usually re-TURP, has been reported at a constant annual rate of approximately 1-2%. A review analysing 29 RCTs found a retreatment rate of 2.6% after a mean follow-up of sixteen months [283]. A meta-analysis of six trials showed that re-operation was more common after TUIP (18.4%) than after M-TURP (7.2%) [282].

Tolerability and safety: Peri-operative mortality and morbidity have decreased over time, but the latter remains considerable (0.1% and 11.1%, respectively) [284]. Data from an Austrian nationwide study of two cohorts totalling 41,059 men submitted to M-TURP showed a 20% reduction in mortality rate over time, to 0.1% at 30 days and 0.5% at 90 days [280, 281].

The risk of TUR-syndrome decreased to < 1.1% [283, 285]. No case has been recorded after TUIP. Data from 10,654 M-TURPs reported bleeding requiring transfusion in 2.9% [284]. The risk after TUIP is negligible. Similar results for M-TURP complications were reported by an analysis of contemporary RCTs using M-TURP as a comparator: bleeding requiring transfusion 2% (0-9%), TUR-syndrome 0.8% (0-5%), AUR 4.5% (0-13.3%), clot retention 4.9% (0-39%), and UTI 4.1% (0-22%) [278]. Long-term complications comprise urinary incontinence, urinary retention and UTIs, bladder neck contracture (BNC), urethral stricture, retrograde ejaculation and ED [283].

Practical considerations: Monopolar-TURP and TUIP are effective treatments for moderate-to-severe LUTS secondary to BPO. The choice should be based primarily on prostate volume (< 30 mL and 30-80 mL suitable for TUIP and M-TURP, respectively). No studies on the optimal cut-off value exist but the complication rates increase with prostate size [284]. The upper limit for M-TURP is suggested as 80 mL (based on Panel expert opinion, under the assumption that this limit depends on the surgeon's experience, choice of resectoscope size and resection speed), as surgical duration increases, there is a significant increase in the rate of complications and the procedure is safest when performed in under 90 minutes [286].

5.3.1.1 Modifications of M-TURP: bipolar TURP

Mechanism of action: Bipolar TURP (B-TURP) addresses a major limitation of M-TURP by allowing performance in normal saline. Contrary to M-TURP, in B-TURP systems, the energy does not travel through the body to reach a skin pad. Bipolar circuitry is completed locally; energy is confined between an active (resection loop) and a passive pole situated on the resectoscope tip ("true" bipolar systems) or the sheath ("quasi" bipolar systems). Prostatic tissue removal is identical to M-TURP. The various bipolar devices available differ in the way in which current flow is delivered [287, 288]. Prostatic tissue removal is identical to M-TURP.

Efficacy: Bipolar TURP is the most widely and thoroughly investigated alternative to M-TURP. Results from 56 RCTs have been reported [289], of which around half have been pooled in RCT-based meta-analyses [278, 290-294]. Early pooled results concluded that no clinically relevant differences exist in short-term efficacy (IPSS, QoL score and Q_{max}) [291]. Subsequent meta-analyses supported these conclusions though trial quality was generally poor [278, 290, 292-294]. Data from RCTs with mid- to long-term follow-up (up to 60 months) showed no differences in efficacy parameters [295-303].

A meta-analysis was conducted to evaluate the quasi-bipolar transurethral resection in saline (TURis, Olympus Medical) system vs. M-TURP, ten unique RCTs (1,870 patients) were included. It was concluded that TURis was of equivalent efficacy to M-TURP [304].

Tolerability and safety: Early pooled results concluded that no differences exist in short-term urethral stricture/BNC rates, but B-TURP is preferable due to a more favourable peri-operative safety profile (elimination of TUR-syndrome; lower clot retention/blood transfusion rates; shorter irrigation, catheterisation, and possibly hospitalisation times) [291]. Subsequent meta-analyses supported these conclusions [278, 290, 292-294]. However, trial quality was relatively poor and limited follow-up might cause under-reporting of late complications, such as urethral stricture/BNC [291]. An RCT based meta-analysis has shown that TURis reduces the risk of TUR-syndrome and the need for blood transfusion compared to M-TURP [294]. It was concluded that TURis is associated with improved peri-operative safety, eliminating the risk of TUR syndrome (RR: 0.18; 95% CI, 0.05-0.61; p = 0.006), reducing the risk of blood transfusion/clot retention (RR: 0.34; 95% CI, 0.18-0.61; p = 0.0003 and 0.43; 95% CI, 0.22-0.86; p = 0.0161, respectively), and hospital stay (MD: 0.56 d; 95% CI, 0.77 - 0.35; p < 0.0001). No significant difference was detected in urethral stricture rates.

Data from the vast majority of individual RCTs with mid- to long-term follow-up (up to 60 months), showed no differences in urethral stricture/BNC rates [295-303], in accordance with all published meta-analyses. However, two individual RCTs have shown opposing results [302, 305]. A significantly higher stricture (urethral stricture + BNC) rate was detected in the B-TURP arm performed with a "quasi" bipolar system (TURis, Olympus Medical) in patients with a prostate volume > 70 mL at 36 months follow up (9/23 [39.1%] vs. 1/22 [4.6%]; p = 0.01) [302]. In addition, a significantly higher BNC, but not urethral stricture, rate was detected in the B-TURP arm performed with a "true" bipolar system (Gyrus PK SuperPulse, Olympus Medical) in 137 patients followed up to twelve months (0.0% vs. 8.5%; p = 0.02) [305].

Randomised controlled trials using the erectile function domain of the IIEF (IIEF-ED) and the ejaculatory domain of the male sexual-health questionnaire (Ej-MSHQ) showed that M-TURP and B-TURP have a similar effect on erectile and ejaculatory function [306, 307]. Comparative evaluations of the effects on overall sexual function, quantified with IIEF-15, showed no differences between B-TURP and M-TURP at twelve months follow-up (erection, orgasmic function, sexual desire, intercourse satisfaction, overall satisfaction) [307, 308].

Practical considerations: Bipolar TURP in patients with moderate-to-severe LUTS secondary to BPO, has similar efficacy with M-TURP, but lower peri-operative morbidity. The duration of improvements with B-TURP were documented in a number of RCTs with mid-term follow-up. Long-term results (up to five years) for B-TURP showed that safety and efficacy are comparable to M-TURP. The choice of B-TURP should be based on equipment availability, surgeon's experience, and patient's preference.

5.3.1.1.1 Modifications of B-TURP: bipolar transurethral vaporisation of the prostate

Mechanism of action: Bipolar transurethral vaporisation of the prostate (B-TUVP) was introduced in the late 1990's ("plasmakinetic" B-TUVP). The technique was derived from plasmakinetic B-TURP and utilised a bipolar electrode and a high-frequency generator to create a plasma effect able to vaporise prostatic tissue [309]. With minimal direct tissue contact (near-contact; hovering technique) and heat production the bipolar electrode produces a constant plasma field (thin layer of highly ionized particles; plasma corona), allowing it to glide over the tissue and vaporise a limited layer of prostate cells without affecting the underlying tissue whilst achieving haemostasis, leaving behind a TURP-like cavity [310]. A distinct difference between B-TUVP and its ancestor (monopolar TUVP), is that B-TUVP displays thinner (< 2 mm) coagulation zones [311], compared to the disproportionate extent of those created by the former (up to 10 mm) [312] that potentially lead to mostly irritative side-effects and stress urinary incontinence [311, 313, 314].

Efficacy: B-TUVP has been evaluated as a TURP alternative for treating moderate-to-severe LUTS in thirteen RCTs to date, including a total of 1,244 men with a prostate size of < 80 mL [298, 315-326]. Early RCTs evaluated the plasmakinetic B-TUVP system [315-319]; however, during the last decade, only the "plasma" B-TUVP system with the "mushroom- or button-like" electrode (Olympus, Medical) has been evaluated [298, 320-326]. Results have been pooled in three RCT-based meta-analyses [278, 327, 328], and a narrative synthesis has been produced in two SRs [278, 329]. The follow up in most RCTs is twelve months [315-318, 320-322, 324, 326]. The longest follow up is 36 months in a small RCT (n = 40) and eighteen months in a subsequent RCT (n = 340); evaluating plasmakinetic [319] and plasma B-TUVP [298], respectively.

Early pooled results concluded that no significant differences exist in short-term efficacy (IPSS, QoL score, Q_{max} and PVR) between plasmakinetic B-TUVP and TURP [278]. However, the promising initial efficacy profile of the former may be compromised by inferior clinical outcomes (IPSS, Q_{max}, re-intervention rate) at mid-term. Larger RCTs with longer follow-up are necessary to draw definite conclusions [278, 319]. A SR of seven RCTs [329] comparing plasmakinetic [315, 317, 318] and plasma B-TUVP [298, 320-322] with TURP concluded that functional outcomes of B-TUVP and TURP do not differ. The poor quality of the included RCTs and the fact that most data was derived from a single institution was highlighted [329]. A similar SR of eight RCTs [278] comparing both B-TUVP techniques with TURP [298, 315, 316, 318-322] concluded that not enough consistent data suitable for a meta-analysis exists; that main functional results are contradictory; and that heterogeneity of RCTs, non-standardised techniques and methodological limitations do not permit firm conclusions. A meta-analysis [328] of six RCTs [298, 320-322, 324, 325] specifically evaluating plasma B-TUVP vs. TURP, concluded that both techniques result in a similar improvement of LUTS.

Tolerability and safety: Early pooled results concluded that no statistically significant differences exist collectively for intra-operative and short-term complications between plasmakinetic B-TUVP and TURP but peri-operative complications are significantly fewer after B-TUVP [278]. However, the results of a statistical analysis comparing pooled specific complication rates were not directly reported in this meta-analysis [278]. Mid-term safety results (urethral stricture, ED, and retrograde ejaculation) have also been reported to be similar [319], but larger RCTs with longer follow-up are necessary to draw definite conclusions [278, 319]. A SR of seven RCTs [329] comparing plasmakinetic [315, 317, 318] and plasma B-TUVP [298, 320-322] with TURP concluded that most RCTs suggest a better haemostatic efficiency for B-TUVP, resulting in shorter catheterisation (42.5 vs. 77.5 hours) and hospitalisation times (3.1 vs. 4.4 days); however, the poor quality of the included RCTs and the fact that the majority of the data was derived from a single institution was highlighted [329]. A similar SR of eight RCTs [278] comparing both B-TUVP techniques with TURP [298, 315, 316, 318-322] concluded that not enough consistent data suitable for a meta-analysis exists and that heterogeneity of RCTs, non-standardised techniques and methodological limitations do not permit firm conclusions. A meta-analysis [328] of six RCTs [298, 320-322, 324, 325] specifically evaluating plasma B-TUVP vs. TURP, concluded that no significant differences exist between the techniques in overall complication and transfusion rates. However, a statistically significant difference was detected collectively in major complication rates (Clavien 3, 4; including urethral stricture, severe bleeding necessitating re-operation and urinary incontinence) and in the duration of catheterisation favouring plasma B-TUVP.

Practical considerations: B-TUVP and TURP have similar short-term efficacy. Plasmakinetic B-TUVP has a favourable peri-operative profile, similar mid-term safety but inferior mid-term efficacy compared to TURP. Plasma B-TUVP has a lower short-term major morbidity compared to TURP. Randomised controlled trials of higher quality, multicentre RCTs, and longer follow up periods are needed to evaluate B-TUVP in comparison to TURP.

Summary of evidence	**LE**
Monopolar TURP is the current standard surgical procedure for men with prostate sizes of 30-80 mL and bothersome moderate-to-severe LUTS secondary of BPO.	1
Transurethral incision of the prostate shows similar efficacy and safety to M-TURP for treating moderate-to-severe LUTS secondary to BPO in men with prostates < 30 mL.	1
No case of TUR-syndrome has been recorded, the risk of bleeding requiring transfusion is negligible and retrograde ejaculation rate is significantly lower after TUIP, but the re-operation rate is higher compared to M-TURP.	1
Bipolar TURP achieves short-, mid- and long-term results comparable with M-TURP, but B-TURP has a more favourable peri-operative safety profile.	1b
Bipolar TUVP and TURP have similar short-term efficacy.	1
Plasmakinetic B-TUVP has a favourable peri-operative profile, similar mid-term safety but inferior mid-term efficacy compared to TURP.	1
Plasma B-TUVP has a lower short-term major morbidity rate compared to TURP.	1

The choice between TUIP and TURP should be based primarily on prostate volume (< 30 mL and 30-80 mL suitable for TUIP and TURP, respectively).	4

Recommendations	Strength rating
Offer transurethral incision of the prostate to surgically treat moderate-to-severe LUTS in men with prostate size < 30 mL, without a middle lobe.	Strong
Offer bipolar- or monopolar-transurethral resection of the prostate (TURP) to surgically treat moderate-to-severe LUTS in men with prostate size of 30-80 mL.	Strong
Offer bipolar transurethral vaporisation of the prostate as an alternative to monopolar TURP to surgically treat moderate-to-severe LUTS in men with prostate size of 30-80 mL.	Weak

5.3.2 ***Open prostatectomy***

Mechanism of action: Open prostatectomy is the oldest surgical treatment for moderate-to-severe LUTS secondary to BPO. Obstructive adenomas are enucleated using the index finger, approaching from within the bladder (Freyer procedure) or through the anterior prostatic capsule (Millin procedure). It is used for substantially enlarged glands (> 80-100 mL).

Efficacy: Open prostatectomy reduces LUTS by 63-86% (12.5-23.3 IPSS points), improves QoL score by 60-87%, increases mean Q_{max} by 375% (+16.5-20.2 mL/s), and reduces PVR by 86-98% [330-334]. Efficacy is maintained for up to six years [335].

Two RCT-based meta-analyses evaluated the overall efficacy of OP vs. endoscopic enucleation of the prostate (EEP) for treating patients with large glands [336, 337]. The larger study included RCTs involving 758 patients [337]. Five RCTs compared OP with HoLEP [330, 331, 338] and four RCTs compared OP with EEP using bipolar circuitry [335, 339-341]. Open prostatectomy was performed via a transvesical approach in all RCTs. At 3-, 6-, 12- and 24-month follow-up, there were no significant differences in Q_{max} between EEP and OP. Post-void residual, PSA, IPSS and QoL score also showed no significant difference at 1-, 3-, 6- and 12-months. Furthermore, IIEF also showed no significant difference at 3-, 6- and 12- months. It was concluded that EEP appears to be an effective minimally invasive option for treating large prostates.

Tolerability and safety: Open prostatectomy mortality has decreased significantly during the past two decades (< 0.25%) [334]. Data from an Austrian nationwide study of two cohorts totalling 1,286 men submitted to OP showed mortality rates of 0.2% at 30 days and 0.4% at 90 days. The endourological re-intervention rates after primary OP were 0.9%, 3.0%, 6.0%, and 8.8%, at three months, one year, five years, and eight years, respectively. The respective incidence of re-TURP was 0.5%, 1.8%, 3.7% and 4.3%, respectively [281]. The estimated transfusion rate is about 7-14% [330, 333, 334, 336]. Long-term complications include transient urinary incontinence (up to 10%), BNC and urethral stricture (about 6%) [330-332, 336, 342].

Two recent RCT-based meta-analyses evaluated the overall safety of OP vs. EEP for treating patients with large glands [336, 337]. Operation time was significantly longer for EEP, due to the significantly longer operation time needed for HoLEP (no difference was detected between OP and EEP using bipolar circuitry). Catheterisation and hospitalisation time was significantly shorter with EEP whilst IIEF-5 showed no significant difference between OP and EEP at twelve months. Endoscopic enucleation of the prostate was also associated with fewer blood transfusions but there were no significant differences regarding other complications. It was concluded that EEP appears to be a minimally invasive option for treating large prostates.

Practical considerations: Open prostatectomy is the most invasive surgical method, but it is an effective and durable procedure for the treatment of LUTS/BPO. In the absence of an endourological armamentarium including a holmium laser or a bipolar system, OP is the surgical treatment of choice for men with prostates > 80 mL.

Summary of evidence	LE
Open prostatectomy is an effective and durable procedure for the treatment of LUTS/BPO but it is the most invasive surgical method.	1b
Endoscopic enucleation of the prostate is an effective minimally invasive alternative for treating moderate-to-severe LUTS secondary to BPO in patients with large prostates.	1
Endoscopic enucleation of the prostate achieves similar short- and mid-term efficacy to OP.	1
Endoscopic enucleation of the prostate has a more favourable peri-operative safety profile compared with OP.	1
Open prostatectomy or EEP such as holmium laser or bipolar enucleation of the prostate are the first choice of surgical treatment in men with a substantially enlarged prostate and moderate-to-severe LUTS.	1

Recommendation	Strength rating
Offer open prostatectomy in the absence of endoscopic enucleation to treat moderate-to-severe LUTS in men with prostate size > 80 mL.	Strong

*5.3.3 **Laser treatments of the prostate***

5.3.3.1 Holmium laser enucleation and holmium laser resection of the prostate

Mechanism of action: The holmium:yttrium-aluminium garnet (Ho:YAG) laser (wavelength 2,140 nm) is a pulsed solid-state laser that is absorbed by water and water-containing tissues. Tissue coagulation and necrosis are limited to 3-4 mm, which is enough to obtain adequate haemostasis [343].

Efficacy: Meta-analyses of trials on HoLEP vs. TURP found that symptom improvement was comparable [344] and even superior with HoLEP [278, 344, 345]. One RCT comparing HoLEP with TURP in a small number of patients with a seven year follow-up found that the functional long term results of HoLEP were comparable with TURP [346]. Another meta-analysis demonstrated the superiority of HoLEP when compared to TURP with regards to post-operative Q_{max} [278]. A retrospective study of HoLEP with the longest follow-up of up to ten years (mean 62 months) reported durable functional results with low re-operation rates [347]. Randomised controlled trials indicate that HoLEP is as effective as OP for improving micturition in large prostates [330, 331], with similar improvement regarding Q_{max}, IPSS score and re-operation rates after five years [278, 330]. These findings are supported by two meta-analyses [336, 337].

Tolerability and safety: Compared to TURP, HoLEP has shorter catheterisation and hospitalisation times [348, 349]. Three meta-analyses found that HoLEP has shorter catheterisation time and hospital stay, reduced blood loss, and fewer blood transfusions, but a longer operation time compared with TURP [344, 345, 350]. In a meta-analysis, no significant differences were noted between HoLEP and TURP for urethral stricture (2.6% vs. 4.4%), stress urinary incontinence (1.5% vs. 1.5%), and re-intervention (4.3% vs. 8.8%) [351]. Holmium laser enucleation of the prostate is superior to OP for blood loss, catheterisation and hospitalisation time [330, 331].

Holmium laser enucleation of the prostate has been safely performed in patients using anticoagulant and/or antiplatelet medications [352]. However, current limitations include: a lack of RCTs; limited data on short- and mid-term complications and bridging therapy; data presentation does not allow for separate interpretation of either of the two substantially different topics of antiplatelet (AP) and anticoagulant (AC) therapy. No significant differences in pre-operative characteristics were found between 116 patients who did and 1,558 patients who did not receive AC/AP therapy [352]. Intra-operative characteristics showed shorter enucleation time (51 minutes vs. 65 minutes) for patients under AC/AP vs. no AC/AP, respectively. Post-operative outcomes were comparable except for length of hospital stay (27.8 hrs vs. 24 hrs) and duration of continuous bladder irrigation (15 hrs vs. 13.5 hrs) with both in favor of no AC/AP. No difference was seen between the cohorts for post-operative haemoglobin drop or transfusion rate. With regard to surgical revision two patients (1.9%) in the AC/AP cohort vs. ten patients (0.7%) in the no AC/AP cohort required clot evacuation [352]. Another study of 160 patients on single or dual anti-platelet therapy, who were part of a larger study of > 1000 patients, showed that HoLEP was as effective in patients on anti-platelet therapy with no significant difference in complication rates [353].

The impact on erectile function and retrograde ejaculation is comparable between HoLEP and TURP/OP [331, 354, 355]. Erectile function did not decrease from baseline in either group; three quarters of sexually active patients had retrograde ejaculation after HoLEP. Data have shown that ejaculation and orgasm perception are the two most impacted domains after HoLEP [356]. Attempts to maintain ejaculatory function with HoLEP have been reported to be successful in up to 46.2% of patients [357].

Practical considerations: HoLEP requires experience and relevant endoscopic skills. The experience of the surgeon was the most important factor affecting the overall occurrence of complications [358, 359]. Mentorship programmes are advised to improve surgical performance from both an institutional and personal learning curve perspective [360, 361]. With the advent of HoLEP and the fact that no relevant publications on HoLRP have been published since 2004, HoLRP of the prostate does not play a role in contemporary treatment algorithms.

5.3.3.1.1 Summary of evidence and recommendations for HoLEP

Summary of evidence	LE
Laser enucleation of the prostate using Ho:YAG laser (HoLEP) demonstrates higher haemostasis and intra-operative safety when compared to TURP and OP. Peri-operative parameters like catheterisation time and hospital stay are in favour of HoLEP.	1a

Laser enucleation of the prostate using Ho:YAG laser (HoLEP) did not negatively affect erectile function.	1a
The long-term functional results of HoLEP are comparable to OP.	1a

Recommendation	Strength rating
Offer laser enucleation of the prostate using Ho:YAG laser (HoLEP) to men with moderate-to-severe LUTS as an alternative to transurethral resection of the prostate or open prostatectomy.	Strong

5.3.3.2 532 nm ('Greenlight') laser vaporisation of the prostate

Mechanism of action: The Potassium-Titanyl-Phosphate (KTP) and the lithium triborate (LBO) lasers work at a wavelength of 532 nm. Laser energy is absorbed by haemoglobin, but not by water. Vaporisation leads to immediate removal of prostatic tissue. Three "Greenlight" lasers exist, which differ not only in maximum power output, but more significantly in fibre design and the associated energy tissue interaction of each. The standard Greenlight device is the 180-W XPS laser, but the majority of evidence is published with the former 80-W KTP or 120-W HPS (LBO) laser systems.

Efficacy and safety: A meta-analysis of the nine available RCTs comparing photoselective vaporisation of the prostate (PVP) using the 80-W and 120-W lasers with TURP was performed in 2012 [362]. No differences were found in Q_{max} and IPSS between 80-W PVP and TURP, but only three RCTs provided sufficient twelve month data to be included in the meta-analysis [363-365]. Another meta-analysis from 2016, of four RCTs including 559 patients, on the 120-W laser, demonstrated no significant difference in functional and symptomatic parameters at 6-, 12-, and 24-month follow-up when compared to TURP [366].

The 180-W XPS laser is non-inferior to TURP in terms of IPSS, Q_{max}, PVR volume, prostate volume reduction, PSA decrease and QoL questionnaires. The 180-W XPS laser prostatectomy is superior to TURP in terms of catheterisation time, length of hospital stay and time to stable health status [367].

The longest RCT comparing the 120-W HPS laser with TURP had a follow-up of 36 months and showed a comparable improvement in IPSS, Q_{max}, and PVR [368]. The re-operation rate was significantly higher after PVP (11% vs. 1.8%; p = 0.04) [368]. Similar improvements in IPSS, QoL, Q_{max}, or urodynamic parameters were reported from two RCTs with a maximum follow-up of 24 months [364, 369].

The only available RCT for the 180-W laser reported efficacy and safety outcomes similar to TURP with stable results at 24 months follow-up; however, there was a higher retreatment rate after 24 months in the PVP arm [367].

One RCT comparing HoLEP to PVP, in patients with prostates > 60 mL, showed comparable symptom improvement, but significantly higher flow rates and lower PVR volume after HoLEP at short-term follow-up; in addition, PVP showed a 22% conversion rate to TURP [370].

Tolerability and safety: A meta-analysis of the RCTs comparing the 80-W and 120-W lasers with TURP showed a significantly longer operating time, but shorter catheterisation time and length of hospital stay after PVP [278]. Blood transfusions and clot retention were less with PVP. No difference was noted in post-operative urinary retention, infection, meatal stenosis, urethral stricture, or bladder neck stenosis [278]. In a meta-analysis including trials with the 120-W laser, patients in the PVP group demonstrated significantly lower transfusion rates, shorter catheterisation time and shorter duration of hospital stay compared to TURP. Re-operation rates and operation time were in favour of TURP. No significant differences were demonstrated for treatment for urethral stricture, BNC, incidence of incontinence and infection [366].

According to the Goliath Study, 180-W Greenlight laser prostatectomy is non-inferior to TURP in terms of peri-operative complications. Re-operation free survival during 24 months follow up was comparable between the TURP-arm and the 180-W XPS laser-arm [367].

Based mostly on case series the 80-,120- and 180-W Greenlight laser appears to be safe in high-risk patients undergoing anticoagulation treatment [371-374]; however, patients under anticoagulation therapy were either excluded from or represented a very small sample in currently available RCTs. In one study, anticoagulant patients had significantly higher rates of bladder irrigation (17.2%) compared with those not taking anticoagulants (5.4%) [374]. In contrast, another retrospective study focusing on the 180-W LBO laser did not find any significant differences between patients receiving or not receiving anticoagulants [375]. A retrospective study of a mixed cohort of patients, treated with 80-W KTP PVP and 120-W LBO HPS, revealed that delayed gross haematuria was common in patients (33.8%) during an average follow-up of 33 months [376]. Of these 8.5% presented in the emergency department, 4.8% needed hospitalisation, and surgical revision was required in 4.5%. Multivariate analysis revealed that the odds of bleeding increased with prostate size longer follow-up and anticoagulant use and decreased with increasing age and use of a 5-ARIs

[376]. Available data are further hampered by the absence of details about anticoagulation management in the peri-operative setting (i.e. interruption, bridge or continuation). A retrospective review of a database of patients undergoing 180-W PVP, without interruption of anticoagulation therapy, had a 30.5% rate of peri-operative adverse events with a significant occurrence of high grade Clavien Dindo events [377]. Having significantly more comorbidities, this group of patients also had significantly longer lengths of hospital stay and catheterisation time.

Safety in patients with urinary retention, impaired detrusor contractility, elderly patients or prostates > 80 mL was shown in various prospective short-term non-randomised trials. No RCT including prostates > 100 mL has been reported; therefore, comparison of retreatment rates between prostate volumes of different sizes is not possible [378-380].

An RCT with twelve months follow-up reported a retrograde ejaculation rate of 49.9% following PVP with an 80-W laser vs. 56.7% for TURP, there was no impact on erectile function in either arm of the trial [381]. Additional studies have also reported no difference between OP/TURP and Greenlight PVP for erectile function [382, 383]. However, IIEF-5 scores were significantly decreased at 6-, 12-, and 24- months in patients with pre-operative IIEF-5 greater than 19 [384].

Practical considerations: The 180-W XPS represents the current standard of generators for PVP; however, the number and quality of supporting publications are low, especially for large glands (> 100 mL), with no long-term follow-up.

5.3.3.2.1 Summary of evidence and recommendations for 532 nm ('Greenlight') laser vaporisation of prostate

Summary of evidence	**LE**
Laser vaporisation of the prostate using the 80-W KTP and the 120-W LBO laser (PVP) demonstrated higher intra-operative safety with regard to haemostatic properties when compared to TURP. Peri-operative parameters such as catheterisation time and hospital stay are in favour of PVP, whereas operation time and risk of re-operation are in favour of TURP. Short-term results for the 80-W KTP laser and mid-term results for the 120-W LBO laser were comparable to TURP.	1a
Laser vaporisation of the prostate using the 180-W LBO laser (PVP) demonstrated higher intra-operative safety with regard to haemostatic properties when compared to TURP. Peri-operative parameters such as catheterisation time and hospital stay were in favour of PVP, whereas operation time was in favour of TURP. Short- to mid-term results are comparable to TURP.	1b
Laser vaporisation of the prostate using the 80-W KTP and 120-W LBO lasers seems to be safe for the treatment of patients receiving antiplatelet or anticoagulant therapy.	2
Laser vaporisation of the prostate using the 180-W LBO laser seems to be safe for the treatment of patients receiving antiplatelet or anticoagulant therapy; however, the level of available evidence is low.	3

Recommendations	**Strength rating**
Offer 80-W 532-nm Potassium-Titanyl-Phosphate (KTP) laser vaporisation of the prostate to men with moderate-to-severe LUTS with a prostate volume of 30-80 mL as an alternative to transurethral resection of the prostate (TURP).	Strong
Offer 120-W 532-nm Lithium Borat (LBO) laser vaporisation of the prostate to men with moderate-to-severe LUTS with a prostate volume of 30-80 mL as an alternative to TURP.	Strong
Offer 180-W 532-nm LBO laser vaporisation of the prostate to men with moderate-to-severe LUTS with a prostate volume of 30-80 mL as an alternative to TURP.	Strong
Offer laser vaporisation of the prostate using 80-W KTP, 120- or 180-W LBO lasers for the treatment of patients receiving antiplatelet or anticoagulant therapy with a prostate volume < 80 mL.	Weak

5.3.3.3 Diode laser treatment of the prostate

Mechanism of action: For prostate surgery, diode lasers with a wavelength of 940, 980, 1,318, and 1,470 nm (depending on the semiconductor used) are marketed for vaporisation and enucleation. Only a few have been evaluated in clinical trials [385].

Efficacy: Two RCTs for 120-W 980 nm diode laser vaporisation vs. M-TURP are available [386, 387]. The first RCT with 24 month follow-up reported equal symptomatic and clinical parameters at one and six months. However, at 12- and 24-months the results were significantly in favour of TURP, repeat TURP was more frequent in the diode laser group [386]. The second RCT reported equivocal results for both interventions at 3-month follow-up [387].

Three RCTs with a twelve month follow-up compared 980 nm diode laser enucleation with bipolar enucleation and found no significant difference with regard to clinical outcome [388-390]. One small RCT with a six month follow-up comparing laser enucleation using a 1,318 nm diode laser with B-TURP reported similar efficacy [391]. An RCT of 154 patients undergoing 1,470 nm diode laser enucleation of the prostate (DiLEP) or plasmakinetic resection of the prostate (PKRP) revealed no difference in post-operative IPSS, QoL, Q_{max}, and PVR, however DiLEP had decreased risk of hemorrhage, operative time, bladder irrigation time, catheterisation duration, and hospital stay [392].

A one year RCT comparing transurethral endoscopic enucleation of the prostate using a 980 nm diode laser vs. bipolar plasmakinetic enucleation (BEEP) for the treatment of LUTS/BPO in 111 patients showed equivalence for both procedures. Post-operative results for DiLEP were comparable to BEEP regarding Q_{max} (28.0 ± 7.0 vs. 28.1 ± 7.2 mL/s) and IPSS (3.0 ± 2.2 vs. 2.9 ± 2.6) at twelve months. There was also no significant difference in tissue removal (71.8% vs. 73.8%) and complications at twelve months [390].

Tolerability and safety: Published studies on 980 nm laser vaporisation indicate high haemostatic potential, although anticoagulants or platelet aggregation inhibitors were taken in 24% and 52% of patients, respectively [393, 394]. In a number of studies, a high rate of post-operative dysuria was reported [386, 393-395]. In an RCT reflecting on peri-operative and post-operative complications no significant differences were demonstrated for clot retention, re-catheterisation, UUI and UTI [386]. Moreover, for late complications no significant differences could be demonstrated for re-operation rate, urethral stricture, bladder neck sclerosis, *de novo* sexual dysfunction and mean time of dysuria [386].

Fibre modifications can potentially reduce surgical time [396]. Early publications on diode vaporisation reported high re-operation rates (8-33%) and persisting stress urinary incontinence (9.1%) [386, 393-395]. In contrast, the four RCTs on diode laser enucleation showed that blood loss, hospitalisation and catheterisation time were in favour of diode laser enucleation, with equivalent clinical outcome for either bipolar enucleation [388-390] or TURP [391] during short-term follow-up.

Practical considerations: Diode laser vaporisation leads to similar improvements in clinical and symptomatic parameters during short-term follow-up and provides good haemostatic properties. Diode laser enucleation seems to offer similar efficacy and safety when compared to either TURP or bipolar enucleation. Based on the limited number, mainly low quality RCTs, and controversial data on the retreatment rate, results for diode laser vaporisation and enucleation should be evaluated in further higher quality RCTs.

5.3.3.3.1 Summary of evidence and recommendations for diode laser treatment of the prostate

Summary of evidence	**LE**
Laser vaporisation of the prostate using the 120-W 980 nm laser demonstrated high intra-operative safety with regard to haemostatic properties when compared to TURP. Peri-operative parameters like catheterisation time and hospital stay were in favour of diode lasers. Short-term results are comparable to TURP.	1b
In a number of studies severe post-operative complications such as severe storage symptoms or persisting incontinence occurred with laser vaporisation of the prostate using the 120-W 980 nm diode laser.	3
Laser enucleation of the prostate using the 980 nm laser showed comparable efficacy to bipolar endoscopic enucleation in the short term. Peri-operative parameters like blood loss, catheterisation time and hospital stay were in favour of diode enucleation.	1b
Laser vaporisation using the 120-W 980 nm diode laser seems to be safe with regard to haemostasis in patients receiving anticoagulant therapy.	3

Recommendations	**Strength rating**
Offer 120-W 980 nm diode laser vaporisation of the prostate to men with moderate-to-severe LUTS as a comparable alternative to transurethral resection of the prostate (TURP).	Weak
Offer 120-W 980 nm diode laser or 1,318 nm diode laser enucleation of the prostate to men with moderate-to-severe LUTS as a comparable alternative to TURP or bipolar enucleation.	Weak

5.3.3.4 Thulium:yttrium-aluminium-garnet laser (Tm:YAG)

Mechanism of action: In the Tm:YAG laser, a wavelength between 1,940 and 2,013 nm is emitted in continuous wave mode. The laser is primarily used in front-fire applications [385, 397]. Different applications, ranging from vaporisation (ThuVAP), vaporesection (ThuVARP), and enucleation (ThuVEP vapoenucleation i.e. excising technique/ThuLEP blunt thereby primarily anatomical enucleation with Tm:YAG support) are published [398-400].

Efficacy: Two meta-analyses compared ThuVARP with TURP. The first meta-analysed data from three RCTs, one quasi-RCT and two case control studies. Studies with mono- or bipolar-TURP were included. Both treatments were efficacious with a difference in IPSS improvement in favour of ThuVARP at twelve months [401]. The second meta-analysis included data from six RCTs and three retrospective studies with different follow-ups and with only B-TURP as the comparator. There was no significant difference in terms of IPSS, Q_{max}, and PVR between the two therapies [402]. An RCT with a four year follow-up comparing ThuVARP to M-TURP, showed comparable efficacy and favourable re-operation rates in the ThuVaRP group [403]. Yang *et al*. demonstrated no significant difference with regard to symptoms and voiding parameters at one, three and five years follow-up [404]. A prospective multicentre study on ThuVARP, including 2,216 patients, showed durable post-operative improvement in IPSS, QoL, Q_{max}, and PVR for the entire eight years of follow-up [405].

There are mainly prospective case studies on ThuVEP showing a significant improvement in IPSS, Q_{max}, and PVR after treatment [406-409]. One RCT with eighteen months follow up showed comparable outcomes in both arms for ThuLEP and HoLEP [410]. Furthermore, ThuLEP and bipolar enucleation were compared in one RCT with twelve months follow-up. The outcome showed no difference with regard to efficacy whilst the decrease in haemoglobin level and catheter time were significantly lower for ThuLEP [411]. An RCT with five years follow-up compared ThuLEP with bipolar TURP. No difference was found between the two procedures in terms of Q_{max}, IPSS, PVR, and QoL; however, the attrition rate was 50% at five years [404].

Tolerability and safety: ThuVARP, ThuLEP and ThuVEP show high intra-operative safety in RCTs [403, 412-414], as well as in case series in patients with large prostates [406] and anticoagulation or bleeding disorders [407, 415, 416]. Catheterisation time, hospital stay, and blood loss were shorter compared to TURP [412, 414, 417, 418]. These results were confirmed in the two meta-analyses comparing ThuVARP with TURP [401, 402]. The rate of post-operative urethral strictures after ThuVARP was 1.9%, the rate of BNC was 1.8%, and the re-operation rate was 0-7.1% during follow-up [412, 417, 419]. Urethral stricture after ThuVEP occurred in 1.6%, and the overall retreatment rate was 3.4% (mean follow-up 16.5 months) [399]. No urethral and bladder neck strictures after ThuLEP were reported during the eighteen months follow-up [413]. Recently, a study focusing on post-operative complications after ThuVEP reported adverse events in 31% of cases, with 6.6% complications greater then Clavien grade 2 [420]. One case control study on ThuVEP with 48-month follow-up reported long-term durability of voiding improvements and overall re-operation rates of 2.4% [415]. Two studies (one case control, one RCT vs. TURP) addressed the impact of ThuVEP on sexual function, demonstrating no effect on erectile function with increased prevalence of retrograde ejaculation post-operatively [421, 422]. Another case control study evaluated the impact of thulium laser prostatectomy (resection and vapoenucleation) on erectile function. The IIEF-5 scores dropped significantly during the first three post-operative months and then gradually increased returning to pre-operative levels at the twelve month follow-up assessment [423].

Urethral stricture and BNC was 2.6% and 1.6%, respectively in a prospective multicentered study of ThuVARP. Persistent stress incontinence was found in 0.1% whilst, re-operation due to BPH recurrence was required in 1.2% patients [405].

In two RCTs on ThuLEP vs. TURP [424], one RCT on ThuLEP vs. bipolar enucleation [411] and one RCT on ThuLEP vs. HoLEP [410], ThuLEP appeared to be superior with regard to intra-operative haemostasis. The same was demonstrated for ThuVEP vs. TURP in one RCT [414]; however, in two further RCTs on ThuLEP vs. HoLEP no significant difference could be demonstrated at 6, 12 and 18 months follow up [413, 425].

Practical considerations: As a limited number of RCTs and only a few studies with long-term follow-up support the efficacy of thulium laser prostatectomy, there is a need for ongoing investigation of the technique.

5.3.3.4.1 Summary of evidence and recommendations for the use of the Thulium: yttrium-aluminium-garnet laser (Tm:YAG)

Summary of evidence	**LE**
Laser enucleation of the prostate using either vapoenucleating (ThuVEP) or laser assisted blunt technique (ThuLEP) demonstrates high intra-operative safety with regard to haemostatic properties when compared to TURP. Short-term results are comparable to TURP.	1b
Laser vapoenucleation of the prostate using a Tm:YAG laser (ThuVEP) seems to be safe in patients receiving anticoagulant or antiplatelet therapy.	2b
Laser vaporesection of the prostate using Tm:YAG laser (ThuVARP) demonstrates high intra-operative safety with regard to haemostatic properties when compared to TURP. Peri-operative parameters like catheterisation time and hospital stay are in favour of thulium lasers. Long-term results are similar to TURP.	1a

Recommendations	Strength rating
Offer laser enucleation of the prostate using Tm:YAG vapoenucleation (ThuVEP) and Tm:YAG laser assisted anatomical enucleation (ThuLEP) to men with moderate-to-severe LUTS as alternatives to TURP and holmium laser enucleation (HoLEP).	Weak
Offer ThuVEP to patients receiving anticoagulant or antiplatelet therapy.	Weak
Offer laser resection of the prostate using Tm:YAG laser (ThuVARP) as an alternative to TURP.	Strong
Offer ThuVARP to patients receiving anticoagulant or antiplatelet therapy.	Weak

5.3.4 ***Prostatic urethral lift***

Mechanism of action: The prostatic urethral lift (PUL) represents a novel minimally invasive approach under local or general anaesthesia. Encroaching lateral lobes are compressed by small permanent suture-based implants delivered under cystoscopic guidance (Urolift®) resulting in an opening of the prostatic urethra that leaves a continuous anterior channel through the prostatic fossa extending from the bladder neck to the verumontanum.

Efficacy: In general, PUL achieves a significant improvement in IPSS (-39% to -52%), Q_{max} (+32% to +59%) and QoL (-48% to -53%) [426-431]. Prostatic urethral lift was initially evaluated vs. sham in a multicentre study with one [428] three [432] and five [433] years follow-up. The primary endpoint was met at three months with a 50% reduction in IPSS. In addition, Q_{max} increased significantly from 8.1 to 12.4 mL/s compared to baseline at three months and this result was confirmed at twelve months. The difference in clinical response for Q_{max} between both groups was of statistical significance. A relevant benefit with regard to PVR was not demonstrated compared to baseline or sham. At three years, average improvements from baseline were significant for total IPSS, QoL, Q_{max} and individual IPSS symptoms. There were no *de novo*, sustained ejaculatory or erectile dysfunction events and all sexual function assessments showed average stability or improvement after PUL. Improvements in IPSS, QoL, BPH impact index (BPHII), and Q_{max} were durable throughout the five years with improvement rates of 36%, 50%, 52%, and 44%, respectively. The re-treatment rate was 13.6% over five years. Adverse events were mild to moderate and transient. Sexual function was stable over five years with no *de novo*, sustained erectile, or ejaculatory dysfunction.

Another RCT of 80 patients was conducted in three European countries, comparing PUL to TURP. At twelve months, IPSS improvement was -11.4 for PUL and -15.4 for TURP. There was no retrograde ejaculation among PUL patients, while 40% of TURP patients lost the ability to ejaculate. Surgical recovery was measured using a validated instrument and confirmed that recovery from PUL is more rapid and more extensive in the first three to six months [434]. However, TURP resulted in much greater improvements in Q_{max} after twelve months compared to PUL. At 24 months, significant improvements in IPSS, IPSS QoL, BPHII, and Q_{max} were observed in both arms. Change in IPSS and Q_{max} in the TURP arm were superior to the PUL arm [435]. Improvements in QoL and BPHII score were not statistically different between the study arms. Prostatic urethral lift resulted in superior quality of recovery and ejaculatory function preservation. Ejaculatory function and bother scores did not change significantly in either treatment arm.

In a meta-analysis of retrospective and prospective trials, pooled estimates showed an overall improvement following PUL, including IPSS, Q_{max}, and QoL [431]. Sexual function was preserved with a small improvement estimated at twelve months.

Tolerability and safety: The most common complications reported post-operatively included haematuria (16-63%), dysuria (25-58%), pelvic pain (5-17.9%), urgency (7.1-10%), transient incontinence (3.6-16%), and UTI (2.9-11%) [428, 431-433]. Most symptoms were mild-to-moderate in severity and resolved within two to four weeks after the procedure.

Prostatic urethral lift seems to have no significant impact on sexual function. Evaluation of sexual function as measured by IIEF-5, Male Sexual Health Questionnaire-Ejaculatory Dysfunction, and Male Sexual Health Questionnaire-Bother in patients undergoing PUL showed that erectile and ejaculatory function were preserved [426-430].

Practical considerations: An obstructed/protruding middle lobe cannot be effectively treated, and the effectiveness in large prostate glands has not been shown yet. Long-term studies are needed to evaluate the duration of the effect in comparison to other techniques.

Summary of evidence	LE
Prostatic urethral lift improves IPSS, Q_{max} and QoL; however, these improvements are inferior to TURP at 24 months.	1b

Prostatic urethral lift has a low incidence of sexual side effects.	1b
Patients should be informed that long-term effects including the risk of retreatment have not been evaluated.	4

Recommendation	Strength rating
Offer Prostatic urethral lift (Urolift®) to men with LUTS interested in preserving ejaculatory function, with prostates < 70 mL and no middle lobe.	Strong

*5.3.5 **Intra-prostatic injections***

Mechanism of action: Various substances have been injected directly into the prostate in order to improve LUTS, these include Botulinum toxin-A (BoNT-A), fexapotide triflutate (NX-1207) and PRX302. The primary mechanism of action of BoNT-A is through the inhibition of neurotransmitter release from cholinergic neurons [436]. The detailed mechanisms of action for the injectables NX-1207 and PRX302 are not completely understood, but experimental data associates apoptosis-induced atrophy of the prostate with both drugs [436].

Efficacy: Results from clinical trials have shown only modest clinical benefits, that do not seem to be superior to placebo, for BoNT-A [437, 438]. A recent SR and meta-analysis showed no differences in efficacy compared with placebo and concluded that there is no evidence of clinical benefits in medical practice [439]. The positive results from Phase II-studies have not be confirmed in Phase III-trials for PRX302 [440, 441]. NX-1207 was evaluated in two multicentre placebo controlled double-blind randomised parallel group trials including a total of 995 patients with a mean follow-up of 3.6 years, IPSS change from baseline was significantly higher and AUR rate was significantly reduced in the treatment arm. The authors concluded that NX-1207 is an effective transrectal injectable for long-term treatment for LUTS and that treated patients have reduced need for further intervention [442].

Safety: Studies including safety assessments have reported only a few mild and self-limiting adverse events for all injectable drugs [436]. A recent SR and meta-analysis showed low incident rates of procedure-related adverse events [439]. Two multicentre placebo controlled double-blind randomised parallel group trials with long-term follow up evaluating NX-1207 detected no significant safety differences between the study arms [442].

Practical considerations: Although experimental evidence for compounds such as BoNT-A and PRX302 were promising for their transition to clinical use positive results from Phase II-studies have not be confirmed in Phase III-trials. Randomised controlled trials against a reference technique are needed to confirm the first promising clinical results of NX-1207

Summary of evidence	LE
Results from clinical trials have shown no clinical benefits for BoNT-A compared to placebo for the management of LUTS due to BPO.	1a
Results from clinical trials have shown clinical benefits for NX-1207 compared to placebo for the management of LUTS due to BPO.	1b

Recommendation	Strength rating
Do not offer intraprostatic Botulinum toxin-A injection treatment to patients with male LUTS.	Strong

*5.3.6 **Techniques under investigation***

Recommendations on new interventions will only be included in the Guidelines once supported by RCTs looking at both efficacy and safety, with adequate follow-up (> 3 yrs), and secondary studies to confirm the reproducibility and generalisability of the first pivotal studies [443]. Otherwise, there is a danger that a single pivotal study can be overexploited by device manufacturers. Studies that are needed include (1) proof of concept, (2) RCTs on efficacy and safety, as well as (3) cohort studies with a broad range of inclusion and exclusion criteria to confirm both reproducibility and generalisability of the benefits and harms [443]. The panel will assess the quality of all RCTs and if they do not meet the standard required the intervention will continue to have no recommendation i.e. a RCT does not guarantee inclusion in the Guidelines. In the current Guideline, a recommendation is given for Aquablation and Prostatic Artery Embolisation (PAE); however, these two techniques should still be considered as under investigation in order to better define their position in the armamentarium of invasive therapies for BPO and to better define the subgroups of patients who will benefit most from them.

5.3.6.1 Minimal invasive simple prostatectomy

Mechanism of action: The term minimal invasive simple prostatectomy (MISP) includes laparoscopic simple prostatectomy (LSP) and robot-assisted simple prostatectomy (RASP). The technique for LSP was first described in 2002 [444], while the first RASP was reported in 2008 [445]. Both LSP and RASP are performed using different personalised techniques, developed based on the transcapsular (Millin) or transvesical (Freyer) techniques of OP. An extraperitoneal approach is mostly used for LSP, while a transperitoneal approach is mostly used for RASP.

Efficacy: A SR and meta-analysis showed that in 27 observational studies including 764 patients, the mean increase in Q_{max} was 14.3 mL/s (95% CI 13.1-15.6), and the mean improvement in IPSS was 17.2 (95% CI 15.2-19.2) [446]. Mean duration of operation was 141 minutes (95% CI 124-159), and the mean intra-operative blood loss was 284 mL (95% CI 243-325). One hundred and four patients (13.6%) developed a surgical complication. In comparative studies to OP, length of hospital stay, length of catheter use and estimated blood loss were significantly lower in the MISP group, while the duration of operation was longer than in OP. There were no differences in improvements in Q_{max}, IPSS and peri-operative complications between both procedures.

Two recent retrospective series on RASP were not included in the meta-analysis which confirm these findings [447, 448]. The largest retrospective series reports 1,330 consecutive cases including 487 robotic (36.6%) and 843 laparoscopic (63.4%) simple prostatectomy cases. The authors confirm that both techniques can be safely and effectively done in selected centres [447].

Tolerability and safety: In the largest series, the post-operative complication rate was 10.6% (7.1% for LSP and 16.6% for RASP), most of the complications being of low grade. The most common complications in the RASP series were haematuria requiring irrigation, UTI and AUR; in the LSP series, the most common complications were UTI, ileus and AUR. In the most recent, largest comparative analysis of robotic vs. open simple prostatectomy (OSP) for large-volume prostates, a propensity score-matched analysis was performed with five covariates. Robotic compared with OSP demonstrated a significant shorter average length of stay (1.5 vs. 2.6 days), but longer mean operative time (161 vs. 93 minutes). The robotic approach was also associated with a lower estimated blood loss (339 vs. 587 mL). Improvements in maximal flow rate, IPSS, QoL, PVR and post-operative PSA levels were similar before and after surgery for both groups. There was no difference in complications between the groups [449].

Practical considerations: Minimal invasive simple prostatectomy seems comparable to OP in terms of efficacy and safety, providing similar improvements in Q_{max} and IPSS [446]. However, most studies are of a retrospective nature. High quality studies are needed to compare the efficacy, safety, and hospitalisation times of MISP and both OP and endoscopic methods. Long-term outcomes, learning curve and cost of MISP should also be evaluated.

Summary of evidence	**LE**
Minimal invasive simple prostatectomy is feasible in men with prostate sizes > 80 mL needing surgical treatment; however, RCTs are needed.	2a

5.3.6.2 (i)TIND

Basic principle: The iTIND is a device designed to remodel the bladder neck and the prostatic urethra and is composed of three elongated struts and an anchoring leaflet, all made of nitinol. Under direct visualisation the iTIND is deployed inside the prostate in expanded configuration. The intended mode of action is to compress obstructive tissue by the expanded device, thereby exerting radial force leading to ischaemic necrosis in defined areas of interest. The iTIND is left in position for five days. The resulting incisions may be similar to a Turner Warwick incision. In an outpatient setting the device is removed by standard urethroscopy.

Efficacy: A single-arm, prospective study of 32 patients with a follow up of three years was conducted to evaluate feasibility and safety of the procedure [450]. The change from baseline in IPSS, QoL score and Q_{max} was significant at every follow-up time point [451].

Tolerability and safety: The device has been reported to be well tolerated by all patients. Four early complications (12.5%) were recorded, including one case of urinary retention (3.1%), one case of transient incontinence due to device displacement (3.1%), and two cases of infection (6.2%). No further complications were recorded during the 36-month follow-up period.

Practical considerations: Randomised controlled trials comparing iTIND to a reference technique are ongoing.

5.3.6.3 Aquablation – image guided robotic waterjet ablation: AquaBeam

Basic principle: AquaBeam uses the principle of hydro-dissection to ablate prostatic parenchyma while sparing collagenous structures like blood vessels and the surgical capsule. A targeted high velocity saline stream ablates prostatic tissue without the generation of thermal energy under real-time transrectal ultrasound guidance. After completion of ablation haemostasis is performed with a Foley balloon catheter on light traction or diathermy or low-powered laser if necessary [452].

Efficacy: In a double-blind, multicentre, prospective RCT 181 patients were randomised to TURP or Aquablation [453]. Mean total operative time was similar for Aquablation and TURP (33 vs. 36 minutes, p = 0.2752), but resection time was lower for Aquablation (4 vs. 27 minutes, p < 0.0001). At six months patients treated with Aquablation and TURP experienced large IPSS improvements (-16.9 and -15.1, respectively). The study non-inferiority hypothesis was satisfied (p < 0.0001). Larger prostates (50-80 mL) demonstrated a more pronounced benefit. At one year follow-up, mean IPSS reduction was 15.1 in the Aquablation group and 15.1 in the TURP group with a mean percent reduction in IPSS score of 67% in both groups. Ninety three percent and 86.7% of patients had improvements of at least 5 points from baseline, respectively. No significant difference in improvement of IPSS, QoL, Q_{max} and reduction of PVR was reported between both groups. One TURP subject (1.5%) and three Aquablation subjects (2.6%) underwent re-TURP within one year of the study procedure [454]. In a cohort study of 101 men with a prostate volume between 80-150 mL mean IPSS improved from 23.2 at baseline to 5.9 at six months. Improvement in IPSS, QoL, Q_{max} and reduction of PVR were also significant at six months. No secondary procedures for tissue removal occurred as of the six months [455].

Tolerability and safety: Aquablation was shown to be non-inferior to TURP (26% vs. 42%, p = 0.0149). Among sexually active men the rate of anejaculation was lower in those treated with Aquablation compared to TURP (10% vs. 36%, respectively). There were no procedure-related adverse events after six months [454]. In patients with a prostate volume between 80-150 mL, bleeding related events were observed in fourteen patients (13.9%) of which eight (7.9%) occurred prior to discharge and six (5.9%) occurred within one month of discharge. Blood transfusions were required in eight (7.9%) patients, return to the theatre for fulguration in three (3.0%) patients, and both transfusion and fulguration in two patients (2.0%). Ejaculatory dysfunction occurred in 19% of sexually active men [455].

Practical considerations: During short-term follow-up, Aquablation provides non-inferior functional outcomes compared to TURP in patients with LUTS and a prostate volume between 30-80 mL. Longer term follow up is necessary to assess the clinical value of Aquablation.

Summary of evidence	**LE**
Aquablation appears to be as effective as TURP both subjectively and objectively; however, there are still some concerns about the best methods of achieving post-treatment haemostasis.	1b

Recommendations	**Strength rating**
Offer Aquablation* to patients with moderate-to-severe LUTS and prostates between 30-80 mL as an alternative to TURP.	Weak
Inform patients about the risk of bleeding and the lack of long-term follow up data.	Strong

** Aquablation remains under investigation*

5.3.6.4 Convective water vapour energy (WAVE) ablation: The Rezum system

Basic principle: The Rezum system uses radiofrequency power to create thermal energy in the form of water vapour, which in turn deposits the stored thermal energy when the steam phase shifts to liquid upon cell contact. The steam disperses through the tissue interstices and releases stored thermal energy onto prostatic tissue effecting cell necrosis. The procedure can be performed in an office based setting. Usually, one to three injections are needed for each lateral lobe and one to two injections may be delivered into the median lobe.

Efficacy: In a multicentre, randomised, controlled study 197 men were enrolled and randomised in a 2:1 ratio to treatment with water vapour energy ablation or sham treatment (rigid cystoscopy with imitated treatment sounds) [456]. At three months relief of symptoms, measured by a change in IPSS and Q_{max} were significantly improved and maintained compared to the sham arm, although only the active treatment arm was followed up to twelve months. No relevant impact was observed on PVR. Quality of life outcome was significantly improved with a meaningful treatment response of 52% at twelve months (p < 0.0001). Further validated objective outcome measures such as BPHII, Overactive Bladder Questionnaire Short Form for OAB bother, and impact on QoL and International Continence Society Male Item Short Form Survey for male incontinence

demonstrated significant amelioration of symptoms at three months follow-up with sustained efficacy throughout the study period of twelve months. The reported two year results in the Rezum cohort arm of the same study and the recently reported four year results confirmed durability of the positive clinical outcome after convective water vapour energy ablation [457, 458]. Surgical retreatment rate was 4.4% over four years [458].

Tolerability and safety: Safety profile was favourable with adverse events documented to be mild to moderate and resolving rapidly. Preservation of erectile and ejaculatory function after convective water vapour thermal therapy was demonstrated utilising validated outcome instruments such as IIEF and Male Sexual Health Questionnaire-Ejaculation Disorder Questionnaire [456].

Practical considerations: Randomised controlled trials against a reference technique are needed to confirm the first promising clinical results and to evaluate mid- and long-term efficacy and safety of water vapour energy treatment.

5.3.6.5 Prostatic artery embolisation

Basic principle: Prostatic artery embolisation can be performed as a day procedure under local anaesthesia with access through the femoral or radial arteries. Digital subtraction angiography displays arterial anatomy and the appropriate prostatic arterial supply is selectively embolised to effect stasis in treated prostatic vessels. Different techniques have been used for PAE. Atherosclerosis, excessive tortuosity of the arterial supply and the presence of adverse collaterals are anatomical obstacles for the technical approach. Cone beam computed tomography can help identify prostatic arteries and prevent off-target embolisation particularly in patients with challenging anatomical configurations [459].

Efficacy: In a prospective multi-centre matched cohort study of 216 PAE patients and 89 TURP patients, PAE achieved a 10-point improvement in primary outcome of IPSS at twelve months compared with a 15-point improvement with TURP and -3.0 in QoL compared with -4.0 with TURP. There was a 28% reduction in prostate volume with PAE [460].

Another retrospective review of 93 patients undergoing PAE for prostates > 80 mL recorded significant changes in prostate volume 141 mL to 98 mL (-31%), IPSS 22 to 7 (-68%) and QoL 4.4 to 1.3 (-71%), Q_{max} 7.7 to 12.8 mL/s (+66%) and PVR 196 mL to 61 mL (-69%) at twelve months. The authors concluded that PAE may be an alternate treatment for patients for whom conventional surgical options are limited or associated with significant morbidity [461].

Two prospective RCTs were conducted for direct comparison of PAE with TURP [462, 463]. Both studies observed significant treatment outcomes for both procedures as compared to baseline values, but TURP was superior when considering urodynamic parameters such as Q_{max} and PVR. Improvement of LUTS as determined by IPSS and QoL was slightly more pronounced after TURP and reduction of prostate volume was significantly more efficient after TURP than PAE.

Another RCT comparing PAE with TURP in 99 patients (48 vs. 51) showed a mean reduction in IPSS from baseline to twelve weeks of –9.23 points after PAE and –10.77 points after TURP. At twelve weeks, PAE was less effective than TURP regarding improvements in Q_{max} (5.19 mL/s vs. 15.34 mL/s), PVR (–86.36 mL vs. –199.98 mL), prostate volume (–12.17 mL vs. –30.27 mL), and desobstructive effectiveness according to pressure flow studies (56% vs. 93%) shift towards less obstructive category; p = 0.003). For secondary outcomes, compared with PAE, procedural time was shorter for TURP, but in PAE patients bladder catheter indwelling time, and duration of hospital stay were significantly shorter [459].

A SR and meta-analysis of thirteen studies of 1,254 PAE patients between 2014 and 2017 showed IPSS improvement of 67%, QoL (64%) and prostate volume reduction of 26%. Quality of life, IPSS, prostate volume, PVR, & IIEF improvements were maintained at three years [464].

Tolerability and safety: In an earlier SR of comparative studies PAE resulted in more adverse events than TURP/OP (41.6% vs. 30.4%, p = 0.044). The frequency of AUR after the procedures was significantly higher in the PAE group (9.4% vs. 2.0%, p = 0.006) [465]. Non-comparative studies reported an improvement in IIEF after PAE (weighted mean difference 1.31, 95% CI: 0.82, 1.81).

Another RCT however, reported fewer adverse events occurred after PAE than after TURP (36 vs. 70 events; p = 0.003). For secondary outcomes, PAE showed favourable results in terms of blood loss [459]. A SR and meta-analysis of four studies (506 patients) comparing PAE and TURP found no significant difference in the post-operative complications rate between TURP and PAE [466]. Concerns still exist about non-target embolisation, reported in earlier studies [467]; however, more recent studies report less incidents [460, 468].

Practical considerations: A multidisciplinary team approach of urologists and radiologists is mandatory and patient selection should be done by urologists and interventional radiologists. The investigation of patients with LUTS to indicate suitability for invasive techniques should be performed by urologists only. This technically demanding procedure should only be done by an interventional radiologist with specific mentored training and expertise in PAE [469]. Patients with larger prostates (> 80 mL) may have the most to gain from PAE. The selection of LUTS patients who will benefit from PAE still needs to be better defined. Further data with medium- and long-term follow up are still required and comparison with other minimally invasive techniques would be valuable. However, current evidence of safety and efficacy of PAE appears adequate to support the use of this procedure for men with moderate-to-severe LUTS provided proper arrangements for consent and audit are in place; therefore, a recommendation has been given, but PAE remains under investigation.

Summary of evidence	**LE**
Prostatic artery embolisation is less effective than TURP at improving symptoms and urodynamic parameters such as flow rate.	1a
Procedural time is longer for PAE compared to TURP, but blood loss, catheterisation and hospitalisation time are in favour of PAE.	1b

Recommendations	**Strength rating**
Offer prostatic artery embolisation (PAE)* to men with moderate-to-severe LUTS who wish to consider minimally invasive treatment options and accept less optimal objective outcomes compared with transurethral resection of the prostate.	Weak
Perform PAE only in units where the work up and follow up is performed by urologists working collaboratively with trained interventional radiologists for the identification of PAE suitable patients.	Strong

**PAE remains under investigation*

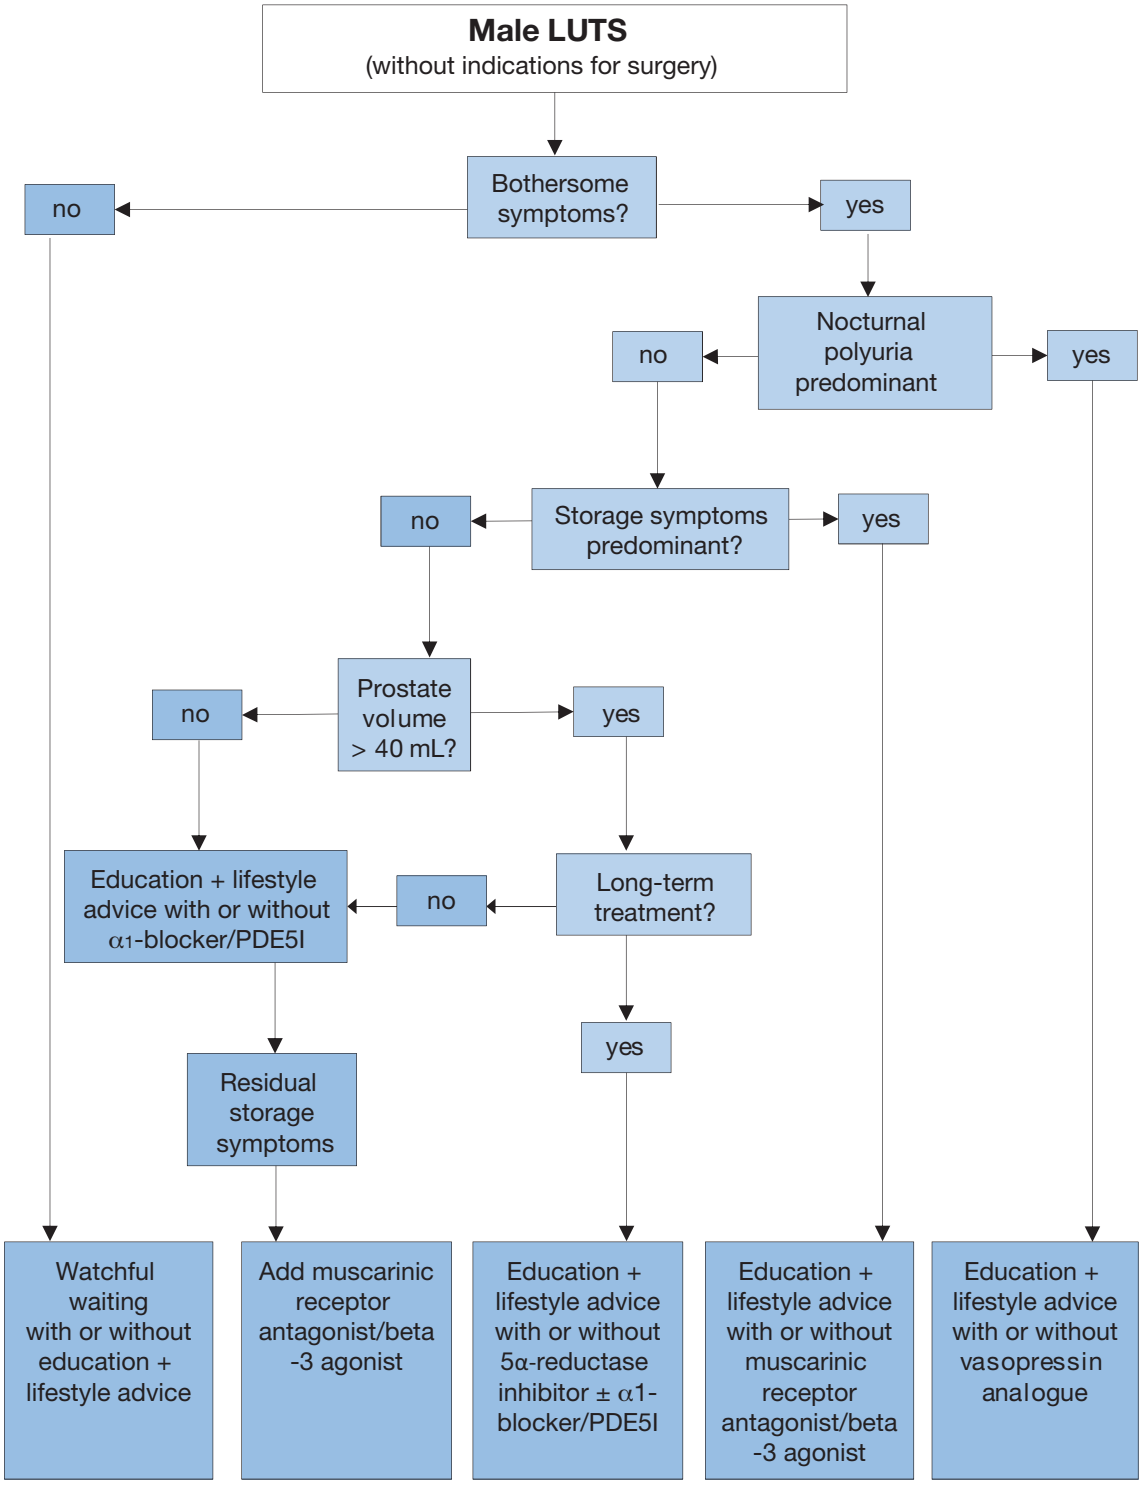
5.4 Patient selection

The choice of treatment depends on the assessed findings of patient evaluation, ability of the treatment to change the findings, treatment preferences of the individual patient, and the expectations to be met in terms of speed of onset, efficacy, side effects, QoL, and disease progression.

Behavioural modifications, with or without medical treatments, are usually the first choice of therapy. Figure 3 provides a flow chart illustrating treatment choice according to evidence-based medicine and patient profiles. Surgical treatment is usually required when patients have experienced recurrent or refractory urinary retention, overflow incontinence, recurrent UTIs, bladder stones or diverticula, treatment-resistant macroscopic haematuria due to BPH/BPE, or dilatation of the upper urinary tract due to BPO, with or without renal insufficiency (absolute operation indications, need for surgery).

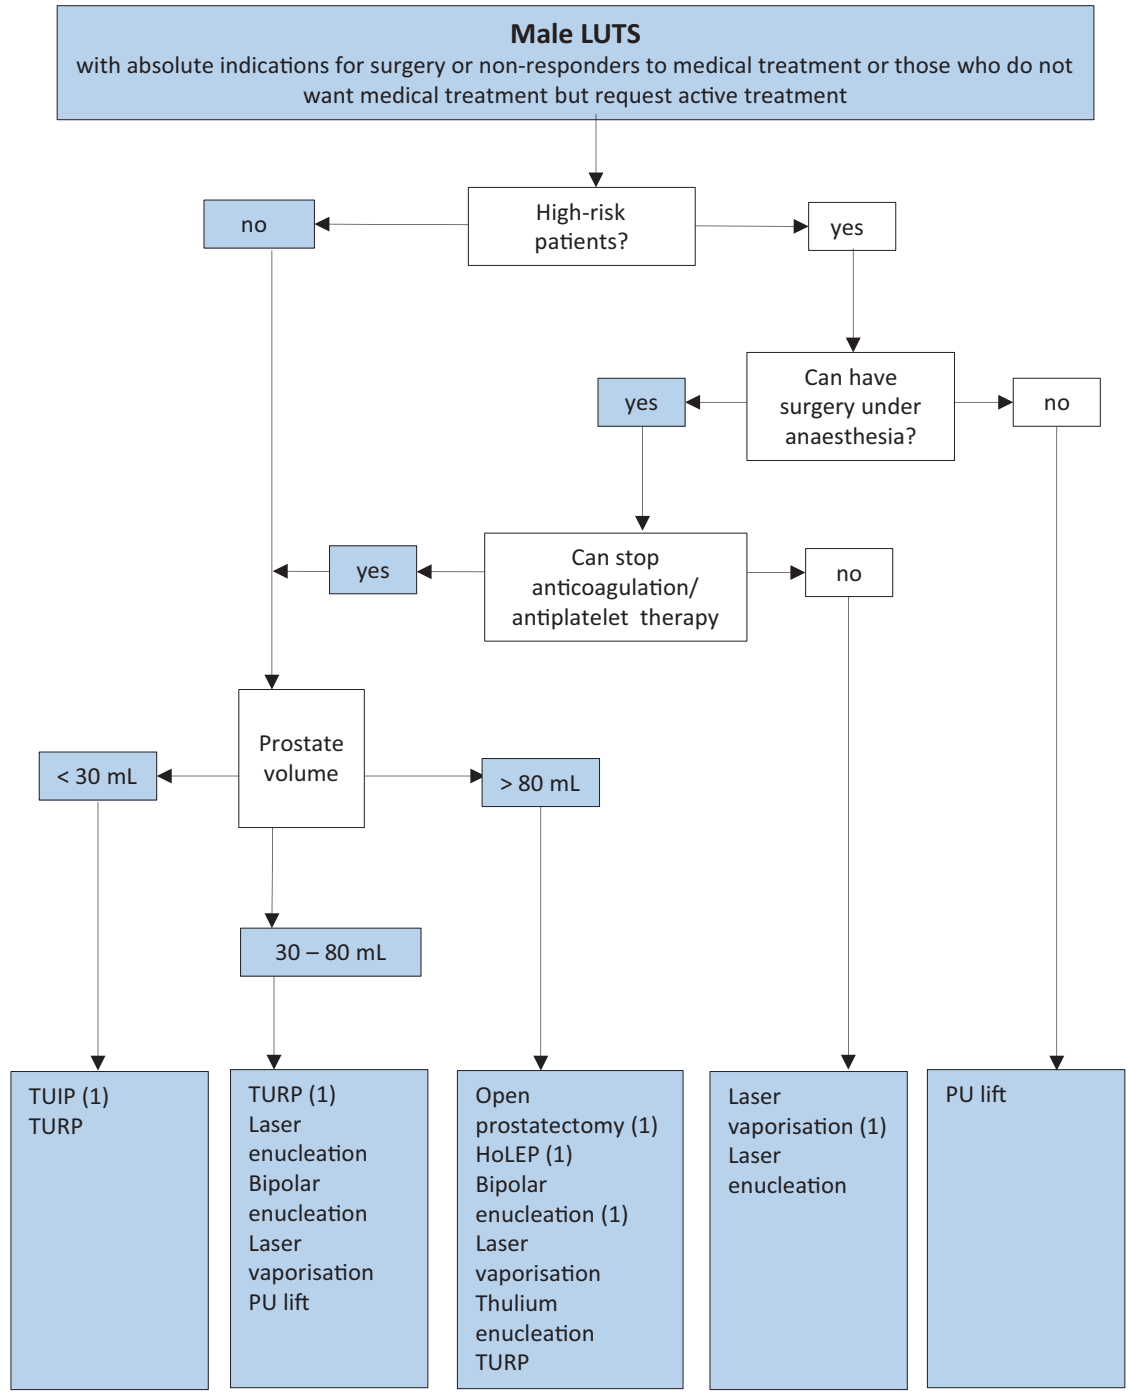
Additionally, surgery is usually needed when patients have not obtained adequate relief from LUTS or PVR using conservative or medical treatments (relative operation indications). The choice of surgical technique depends on prostate size, comorbidities of the patient, ability to have anaesthesia, patients' preferences, willingness to accept surgery-associated specific side-effects, availability of the surgical armamentarium, and experience of the surgeon with these surgical techniques. An algorithm for surgical approaches according to evidence-based medicine and the patient's profile is provided in Figure 4.

Figure 3: Treatment algorithm of male LUTS using medical and/or conservative treatment options. Treatment decisions depend on results assessed during initial evaluation. Note that patients' preferences may result in different treatment decisions.



PDE5I = phosphodiesterase type 5 inhibitors.

Figure 4: Treatment algorithm of bothersome LUTS refractory to conservative/medical treatment or in cases of absolute operation indications. The flowchart is stratified by the patient's ability to have anaesthesia, their cardiovascular risk and prostate size.



(1) Current standard/first choice. The alternative treatments are presented in alphabetical order.
Laser vaporisation includes GreenLight, thulium, and diode laser vaporisation. Laser enucleation includes holmium and thulium laser enucleation.
HoLEP = holmium laser enucleation; TUIP = transurethral incision of the prostate; TURP = transurethral resection of the prostate and PU = prostatic urethral.

5.5 Management of Nocturia in men with lower urinary tract symptoms

The following section reports a SR of therapy for the management of nocturia in men with LUTS. It also emphasises the need to consider the wide range of possible causes of nocturia [470].

Nocturia is defined as the complaint of waking at night to void [5]. It reflects the relationship between the amount of urine produced while asleep, and the ability of the bladder to store the urine received. Nocturia can occur as part of lower urinary tract dysfunction (LUTD), such as OAB and chronic pelvic pain syndrome. Nocturia can also occur in association with other forms of LUTD, such as BOO, but here it is debated whether the link is one of causation or simply the co-existence of two common conditions. Crucially, nocturia may have behavioural, sleep disturbance (primary or secondary) or systemic causes unrelated to LUTD (Table 2). Differing causes often co-exist and each has to be considered in all cases. Only where LUTD is contributory should nocturia be termed a LUTS.

Table 2: Categories of nocturia

CATEGORY	Disproportionate urine production (at all times, or during sleep)	Low volume of each void (at all times, or overnight)
Behavioural	Inappropriate fluid intake	"Bladder awareness" due to secondary sleep disturbance
Systemic	Water, salt and metabolite output	
Sleep disorder	Variable water and salt output	"Bladder awareness" due to primary sleep disturbance
LUTD		Impaired storage function and increased filling sensation

*5.5.1 **Diagnostic assessment***

Evaluation is outlined in Figure 5;

1. Evaluate for LUTD according to the relevant guidelines. The severity and bother of individual LUTS should be identified with a symptom score, supplemented by directed questioning if needed. A validated bladder diary is mandatory.
2. Review whether behavioural factors affecting fluid balance and sleep are contributing.
3. Review of medical history and medications, including directed evaluation for key conditions, such as renal failure, diabetes mellitus, cardiac failure, and obstructive sleep apnoea. If systemic factors or sleep disorders are potentially important, consider involving appropriate medical expertise (see Figure 6). This is appropriate where a known condition is suboptimally managed, or symptoms and signs suggest an undiagnosed condition.

*5.5.2 **Medical conditions and sleep disorders Shared Care Pathway***

Causative categories for nocturia comprise [471]:

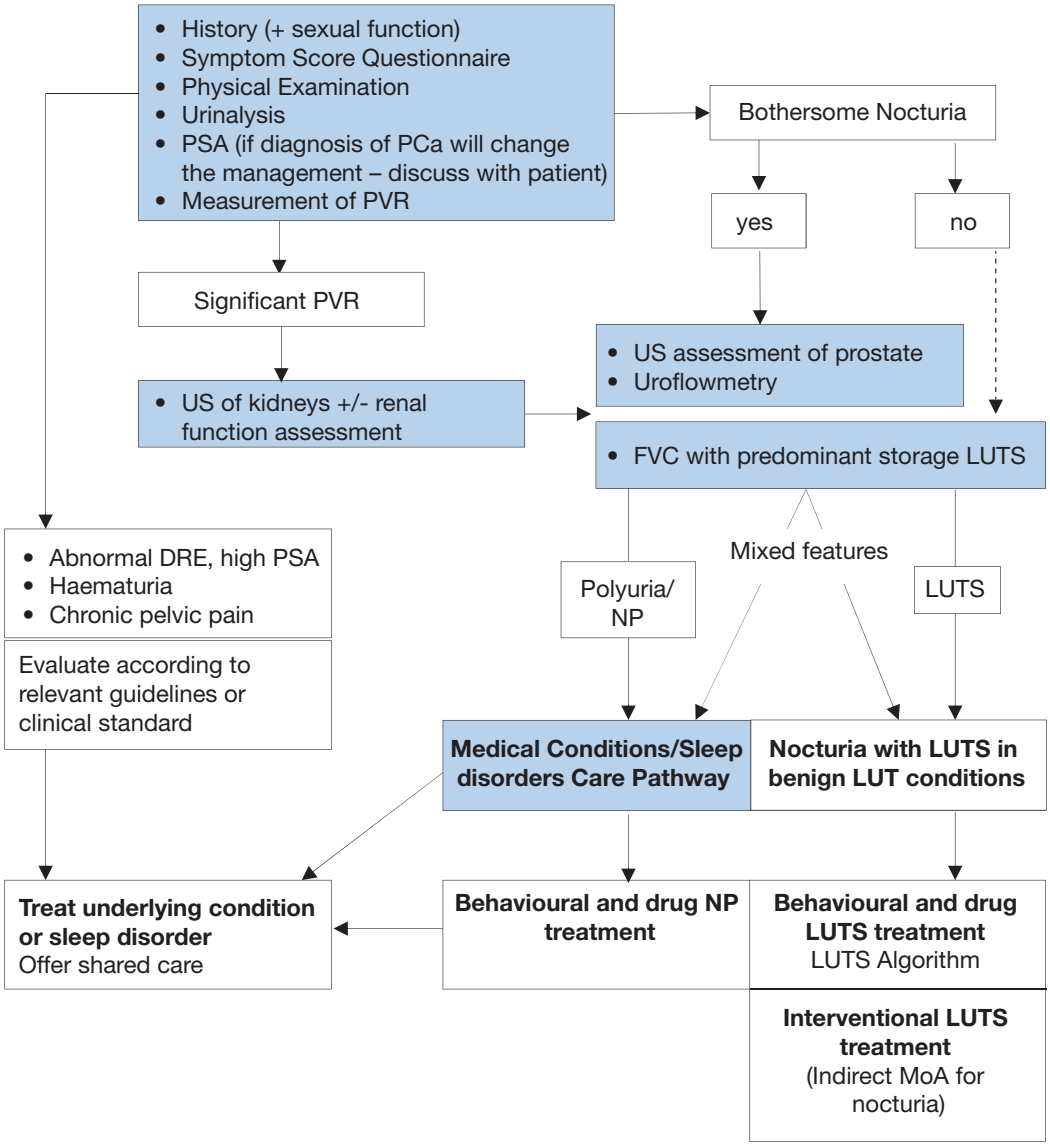
1. bladder storage problems;
2. 24-hour (global) polyuria (> 40 mL/kg urine output over a 24-hour period);
3. nocturnal polyuria (NP; nocturnal output exceeding 20% of 24-hour urine output in the young, or 33% of urine output in people > 65 [5]);
4. sleep disorders;
5. mixed aetiology.

Potentially relevant systemic conditions are those which impair physiological fluid balance, including influences on: levels of free water, salt, other solutes and plasma oncotic pressure; endocrine regulation e.g. by antidiuretic hormone; natriuretic peptides; cardiovascular and autonomic control; renal function; neurological regulation, e.g. circadian regulation of the pineal gland, and renal innervation. As nocturia is commonly referred to the specialty without full insight into cause, the urologist must review the likely mechanisms underlying a presentation with nocturia and instigate review by relevant specialties accordingly. Thus, the managing urologist needs to evaluate nocturia patients in a context where additional medical expertise is available (Table 3). They should not proceed along any LUTD management pathway unless a causative link with LUTD is justifiably suspected, and systemic or sleep abnormalities have been considered.

In patients with non-bothersome nocturia, the medical evaluation (history and physical examination) should consider the possibility of early stages of systemic disease, and whether there is possibility of earlier diagnosis or therapy adjustment.

Some important potentially treatable non-urological causes of nocturia include; obstructive sleep apnoea (OSA), congestive cardiac failure, poorly controlled diabetes mellitus and medications (e.g. diuretics, or lithium).

Figure 5. Evaluation of Nocturia in non-neurogenic Male LUTS.



Assessment must establish whether the patient has polyuria, LUTS, a sleep disorder or a combination. Therapy may be driven by the bother it causes, but non-bothersome nocturia may warrant assessment with a frequency volume chart (indicated by the dotted line) depending on history and clinical examination since potential presence of a serious underlying medical condition must be considered.
FVC = frequency volume chart; DRE = digital rectal examination; NP = nocturnal polyuria; MoA = mechanism of action; PVR = post-void residual; PSA = prostate-specific antigen; US = ultrasound.

Table 3: Shared care pathway for nocturia, highlighting the need to manage potentially complex patients using relevant expertise for the causative factors.

UROLOGICAL CONTRIBUTION	SHARED CARE	MEDICAL CONTRIBUTION
Diagnosis of LUTD • Urological/LUTS evaluation • Nocturia symptom scores • Bladder diary		**Diagnosis of conditions causing NP** • Evaluate patient's known conditions • Screening for sleep disorders • Screening for potential causes of polyuria*
Conservative management Behavioural therapy • Fluid/sleep habits advice • Drugs for storage LUTS • (Drugs for voiding LUTS) • ISC/catherisation Interventional therapy • Therapy of refractory storage LUTS • Therapy of refractory voiding LUTS	**Conservative management** • Antidiuretic • Diuretics • Drugs to aid sleep	**Management** • Initiation of therapy for new diagnosis • Optimised therapy of known conditions * Potential causes of polyuria NEPHROLOGICAL DISEASE • Tubular dysfunction • Global renal dysfunction CARDIOVASCULAR DISEASE • Cardiac disease • Vascular disease ENDOCRINE DISEASE • Diabetes insipidus/mellitus • Hormones affecting diuresis/natriuresis NEUROLOGICAL DISEASE • Pituitary and renal innervation • Autonomic dysfunction RESPIRATORY DISEASE • Obstructive sleep apnoea BIOCHEMICAL • Altered blood oncotic pressure

5.5.3 ***Treatment for Nocturia***

5.5.3.1 Antidiuretic therapy

The antidiuretic hormone arginine vasopressin (AVP) plays a key role in body water homeostasis and control of urine production by binding to V2 receptors in the renal collecting ducts. Arginine vasopressin increases water re-absorption and urinary osmolality, so decreasing water excretion and total urine volume. Arginine vasopressin also has V1 receptor mediated vasoconstrictive/hypertensive effects and a very short serum half-life, which makes the hormone unsuitable for treating nocturia/nocturnal polyuria.

Desmopressin is a synthetic analogue of AVP with high V2 receptor affinity and no relevant V1 receptor affinity. It has been investigated for treating nocturia [472], with specific doses, titrated dosing, differing formulations, and options for route of administration. Most studies have short follow-up. Global interpretation of existing studies is difficult due to the limitations, imprecision, heterogeneity and inconsistencies of the studies.

A SR of randomised or quasi-randomised trials in men with nocturia found that desmopressin may decrease the number of nocturnal voids by -0.46 compared to placebo over short-term follow-up (up to three months); over intermediate-term follow-up (three to twelve months) there was a change of -0.85 in nocturnal voids in a substantial number of participants without increase in major adverse events [473].

Another SR of comparative trials of men with nocturia as the primary presentation and LUTS including nocturia or nocturnal polyuria found that antidiuretic therapy using dose titration was more effective than placebo in relation to nocturnal voiding frequency and duration of undisturbed sleep [470]. Adverse events include headache, hyponatremia, insomnia, dry mouth, hypertension, abdominal pain, peripheral edema, and nausea. Three studies evaluating titrated-dose desmopressin in which men were included, reported seven serious adverse events in 530 patients (1.3%), with one death. There were seventeen cases of hyponatraemia (3.2%) and seven of hypertension (1.3%). Headache was reported in 53 (10%) and nausea in fifteen (2.8%) [470]. Hyponatremia is the most important concern, especially in patients > 65 years of age, with potential life threatening consequences. Baseline values of sodium over 130 mmol/L have been used as inclusion criteria in some research protocols. Assessment of sodium levels must be undertaken at baseline, after initiation of treatment or dose titration and during treatment. Desmopressin is not recommended in high-risk groups [470].

Desmopressin oral disintegrating tablets (ODT) have been studied separately in the sex-specific pivotal trials CS41 and CS40 in patients with nocturia [474, 475]. Almost 87% of included patients had nocturnal polyuria and approximately 48% of the patients were > 65 years. The co-primary endpoints in both trials were change in number of nocturia episodes per night from baseline and at least a 33% decrease in the mean number of nocturnal voids from baseline during three months of treatment. The mean change in nocturia episodes from baseline was greater with desmopressin ODT compared to placebo (difference: women = -0.3 [95% CI: -0.5, -0.1]; men = -0.4 [95% CI: -0.6, -0.2]). The 33% responder rate was also greater with desmopressin ODT compared to placebo (women: 78% vs. 62%; men: 67% vs. 50%).

Analysis of three published placebo-controlled trials of desmopressin ODT for nocturia showed that clinically significant hyponatraemia was more frequent in patients aged ≥ 65 years than in those aged < 65 years in all dosage groups, including those receiving the minimum effective dose for desmopressin (11% of men aged ≥ 65 years vs. 0% of men aged < 65 years receiving 50 mcg; 4% of women ≥ 65 aged years vs. 2% of women aged < 65 years receiving 25 mcg). Severe hyponatraemia, defined as ≤ 125 mmol/L serum sodium, was rare, affecting 22/1,431 (2%) patients overall [476].

Low dose desmopressin (ODT) has been approved in Europe, Canada and Australia for the treatment of nocturia with ≥ 2 episodes in gender-specific low doses 50 mcg for men and 25 mcg for women; however, it initially failed to receive FDA approval, with the FDA citing uncertain benefit relative to risks as the reason. Following resubmission to the FDA in June 2018 desmopressin acetate sublingual tablet, 50 mcg for men and 25 mcg for women, was approved for the treatment of nocturia due to nocturnal polyuria in adults who awaken at least two times per night to void with a boxed warning for hyponatremia.

Desmopressin acetate nasal spray is a new low-dose formulation of desmopressin and differs from other types of desmopressin formulation due to its bioavailability and route of administration. Desmopressin acetate nasal spray has been investigated in two RCTs including men and women with nocturia (over two episodes per night) and a mean age of 66 years. The average benefit of treatment relative to placebo was statistically significant, but low, -0.3 and -0.2 for the 1.5 mcg and 0.75 mcg doses of desmopressin acetate, respectively. The number of patients with a reduction of more than 50% of nocturia episodes was 48.5% and 37.9%, respectively compared with 30% in the placebo group [477]. The reported adverse event rate of the studies was rather low and the risk of hyponatremia was 1.2% and 0.9% for desmopressin acetate 1.5 mcg and 0.75 mcg, respectively. Desmopressin acetate nasal spray was approved by the FDA in 2017 for the treatment of nocturia due to nocturnal polyuria, but it is not available in Europe.

Practical considerations

A complete medical assessment should be made, to exclude potentially non-urological underlying causes, e.g. sleep apnea, before prescribing desmopressin in men with nocturia due to nocturnal polyuria. The optimal dose differs between patients, in men < 65 years desmopressin treatment should be initiated at a low dose (0.1 mg/day) and may be gradually increased up to a dosage of 0.4 mg/day every week until maximum efficacy is reached. Desmopressin is taken once daily before sleeping. Patients should avoid drinking fluids at least one hour before and for eight hours after dosing. Low dose desmopressin may be prescribed in patients > 65 years. In men ≥ 65 years or older, low dose desmopressin should not be used if the serum sodium concentration is below normal: all patients should be monitored for hyponatremia. Urologists should be cautious when prescribing low-dose desmopressin in patients under-represented in trials (e.g. patients > 75 years) who may have an increased risk of hyponatremia.

5.5.3.2 Medications to treat LUTD

Where LUTD is diagnosed and considered causative of nocturia, relevant medications for storage (and voiding) LUTS may be considered. Applicable medications include; selective α1-adrenergic antagonists [478], antimuscarinics [479-481], 5-ARIs [482] and PDE5Is [483]. However, effect size of these medications is generally small, or not significantly different from placebo when used to treat nocturia [470]. Data on OAB medications (antimuscarinics, beta-3 agonist) generally had a female-predominant population. No studies specifically addressing the impact of OAB medications on nocturia in men were identified [470]. Benefits with combination therapies were not consistently observed.

5.5.3.3 Other medications

Agents to promote sleep [484], diuretics [485], non-steroidal anti-inflammatory agents (NSAIDs) [486] and phytotherapy [487] were reported as being associated with response or QoL improvement [470]. Effect size of these medications in nocturia is generally small, or not significantly different from placebo. Larger responses have been reported for some medications, but larger scale confirmatory RCTs are lacking. Agents to promote sleep do not appear to reduce nocturnal voiding frequency, but may help patients return to sleep.

Summary of evidence	LE
No clinical trial of pathophysiology-directed primary therapy has been undertaken.	4
No robust clinical trial of behavioural therapy as primary intervention has been undertaken.	4
Antidiuretic therapy reduces nocturnal voiding frequency in men with baseline severity of ≥ two or more voids per night.	1b
There is an increased risk of hyponatremia in patients 65 years of age or older under antidiuretic therapy.	1b
Antidiuretic therapy increases duration of undisturbed sleep.	1b
α1-blocker use is associated with improvements in undisturbed sleep duration and nocturnal voiding frequency, which are generally of only marginal clinical significance.	2
Antimuscarinic medications can reduce night-time urinary urgency severity, but the reduction in overall nocturia frequency is small or non-significant.	2
Antimuscarinic medications are associated with higher incidence of dry mouth compared with placebo.	2
5α-reductase inhibitors reduce nocturia severity in men with baseline nocturia severity of ≥ two or more voids per night.	2
A trial of timed diuretic therapy may be offered to men with nocturia due to nocturnal polyuria. Screening for hyponatremia should be undertaken at baseline and during treatment.	1b

Recommendations	Strength rating
Treat underlying causes of nocturia, including behavioural, systemic condition(s), sleep disorders, lower urinary tract dysfunction, or a combination of factors.	Weak
Discuss behavioural changes with the patient to reduce nocturnal urine volume and episodes of nocturia, and improve sleep quality.	Weak
Offer desmopressin to decrease nocturia due to nocturnal polyuria in men < 65 years of age.	Weak
Offer low dose desmopressin for men > 65 years of age with nocturia at least twice per night due to nocturnal polyuria.	Weak
Screen for hyponatremia at baseline, day three and day seven, one month after initiating therapy and periodically during treatment. Measure serum sodium more frequently in patients > 65 years of age and in patients at increased risk of hyponatremia.	Strong
Discuss with the patient the potential clinical benefit relative to the associated risks from the use of desmopressin, especially in men > 65 years of age.	Strong
Offer α1-adrenergic antagonists for treating nocturia in men who have nocturia associated with LUTS.	Weak
Offer antimuscarinic drugs for treating nocturia in men who have nocturia associated with overactive bladder.	Weak
Offer 5α-reductase inhibitors for treating nocturia in men who have nocturia associated with LUTS and an enlarged prostate (> 40 mL).	Weak
Do not offer phosphodiesterase type 5 inhibitors for the treatment of nocturia.	Weak

6. FOLLOW-UP

6.1 Watchful waiting (behavioural)

Patients who elect to pursue a WW policy should be reviewed at six months and then annually, provided there is no deterioration of symptoms or development of absolute indications for surgical treatment. The following are recommended at follow-up visits: history, IPSS, uroflowmetry, and PVR volume.

6.2 Medical treatment

Patients receiving α1-blockers, muscarinic receptor antagonists, beta-3 agonists, PDE5Is or the combination of α1-blockers and 5-ARIs or muscarinic receptor antagonists should be reviewed four to six weeks after drug initiation to determine the treatment response. If patients gain symptomatic relief in the absence of troublesome adverse events, drug therapy may be continued. Patients should be reviewed at six months and then annually, provided there is no deterioration of symptoms or development of absolute indications for surgical treatment. The following are recommended at follow-up visits: history, IPSS, uroflowmetry, and PVR volume. Frequency volume charts or bladder diaries should be used to assess response to treatment for predominant storage symptoms or nocturnal polyuria.

Patients receiving 5-ARIs should be reviewed after twelve weeks and six months to determine their response and adverse events. The following are recommended at follow-up visits: history, IPSS, uroflowmetry and PVR volume. Men taking 5-ARIs should be followed up regularly using serial PSA testing if life expectancy is greater than ten years and if a diagnosis of PCa could alter management. A new baseline PSA should be determined at six months, and any confirmed increase in PSA while on 5-ARIs should be evaluated.

In patients receiving desmopressin, serum sodium concentration should be measured at day three and seven, one month after initiating therapy and periodically during treatment. If serum sodium concentration has remained normal during periodic screening follow-up screening can be carried out every three months subsequently. However, serum sodium concentration should be monitored more frequently in patients $\geq$ 65 years of age and in patients at increased risk of hyponatremia. The following tests are recommended at follow-up visits: serum-sodium concentration and FVC. The follow-up sequence should be restarted after dose escalation.

6.3 Surgical treatment

Patients after prostate surgery should be reviewed four to six weeks after catheter removal to evaluate treatment response and adverse events. If patients have symptomatic relief and are without adverse events, no further re-assessment is necessary. The following tests are recommended at follow-up visit after four to six weeks: IPSS, uroflowmetry and PVR volume.

Summary of evidence	LE
Follow-up for all conservative, medical, or operative treatment modalities is based on empirical data or theoretical considerations, but not on evidence-based studies.	4

Recommendations	Strength rating
Follow up all patients who receive conservative, medical or surgical management.	Weak
Define follow-up intervals and examinations according to the specific treatment.	Weak

8. CONFLICT OF INTEREST

All members of the EAU Non-neurogenic Male LUTS Guidelines Panel have provided disclosure statements on all relationships that they have that might be perceived to be a potential source of a conflict of interest. This information is publically accessible through the EAU website: http://www.uroweb.org/guidelines/. These Guidelines were developed with the financial support of the EAU. No external sources of funding and support have been involved. The EAU is a non-profit organisation, and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

9. CITATION INFORMATION

The format in which to cite the EAU Guidelines will vary depending on the style guide of the journal in which the citation appears. Accordingly, the number of authors or whether, for instance, to include the publisher, location, or an ISBN number may vary.

The compilation of the complete Guidelines should be referenced as:
EAU Guidelines. Edn. presented at the EAU Annual Congress Amsterdam 2020. ISBN 978-94-92671-07-3.

If a publisher and/or location is required, include:
EAU Guidelines Office, Arnhem, The Netherlands. http://uroweb.org/guidelines/compilations-of-all-guidelines/

References to individual guidelines should be structured in the following way:
Contributors' names. Title of resource. Publication type. ISBN. Publisher and publisher location, year.

EAU Guidelines on

Urinary Incontinence in Adults

European Association of Urology

TABLE OF CONTENTS PAGE

1. INTRODUCTION

Urinary incontinence (UI) is an extremely common complaint in every part of the world. It causes a great deal of distress and embarrassment, as well as significant costs, to both individuals and societies. Estimates of prevalence vary according to the definition of incontinence and the population studied. However, there is universal agreement about the importance of the problem in terms of human suffering and economic cost.

1.1 Aim and objectives

These Guidelines from the European Association of Urology (EAU) Working Panel on Urinary Incontinence are written by a multidisciplinary group, primarily for urologists, and are likely to be referred to by other professional groups. They aim to provide sensible and practical evidence-based guidance on the clinical problem of UI rather than an exhaustive narrative review. Such a review is already available from the International Consultation on Incontinence [1], and so the EAU Guidelines do not describe the causation, basic science, epidemiology and psychology of UI. The focus of these Guidelines is entirely on assessment and treatment reflecting clinical practice. The Guidelines also do not consider patients with UI caused by neurological disease, or in children, as this is covered by complementary EAU Guidelines [2, 3].

The current Guidelines provide:

- A clear pathway (algorithm) for common clinical problems. This can provide the basis for thinking through a patient's management and also for planning and designing clinical services.
- A brief but authoritative summary of the current state of evidence on clinical topics, complete with references to the original sources.
- Clear guidance on what to do or not to do, in most clinical circumstances. This should be particularly helpful in those areas of practice for which there is little or no high-quality evidence.

In this edition the Panel has continued to focus, largely, on the management of a 'standard' patient. The Panel has referred in places to patients with 'complicated incontinence', by which we mean patients with associated morbidity, a history of previous pelvic surgery, surgery for UI, radiotherapy and women with associated genitourinary prolapse. An appendix is included on non-obstetric genitourinary fistulae. The subject of prevention of UI has not been addressed. A systematic review (SR) on nocturnal incontinence found no studies on the topic. The Panel are of the opinion that nocturnal incontinence should be considered in future research studies.

1.1.1 The elderly

The Panel decided to include a separate but complimentary set of recommendations referring to the elderly population within each section. Older people with UI deserve special consideration for a number of reasons. Physiological changes with natural ageing mean that all types of UI become more common with increasing age. Urinary incontinence commonly co-exists with other comorbid conditions, reduced mobility, and impaired cognition and may require specific interventions, such as assisted toileting.

For the elderly person expectations of assessment and treatment may need to be modified to fit in with specific circumstances, needs, and preferences, while also taking into account any loss of capacity for consent. When the urologist is dealing with a frail elderly patient with urinary incontinence, collaboration with other healthcare professionals such as elderly care physicians is recommended.

It must be emphasised that clinical guidelines present the best evidence available to the experts. However, following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The EAU Urinary Incontinence Panel consists of a multidisciplinary group of experts, including urologists, a gynaecologist and a physiotherapist. All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website: http://www.uroweb.org/guideline/urinary-incontinence.

1.3 Available publications

A quick reference document (Pocket Guidelines) is available, both in print and as an app for iOS and Android devices. These are abridged versions which may require consultation together with the full text versions. Two scientific publications in the journal European Urology are also available [4, 5]. All documents are accessible through the EAU website: http://www.uroweb.org/guideline/urinary-incontinence.

1.4 Publication history

The EAU published the first Urinary Incontinence Guidelines in 2001. Section 4.3 Surgical Management has been completely updated in this 2018 publication.

1.4.1 Summary of changes.

Changed evidence summaries and recommendations can be found in sections:

4.2.6.3 Additional recommendations for antimuscarinic drugs in the elderly

Recommendations	Strength rating
Long-term antimuscarinic treatment should be used with caution in elderly patients especially those who are at risk of, or have, cognitive dysfunction	Strong

SUI = stress urinary incontinence.

4.3.1.6 Recommendations for women with uncomplicated stress urinary incontinence

Recommendations	Strength rating
Inform women about the higher risk of groin pain following a transobturator approach when compared to a retropubic approach.	Strong
Inform women that any vaginal surgery may have an impact on sexual function, which is generally positive.	Weak
Offer bulking agents to women with SUI who request a low-risk procedure with the understanding that repeat injections are likely and long-term durability is not established.	Strong

SUI = stress urinary incontinence.

4.3.1.3.3 Summary of evidence for mid-urethral slings

Summary of evidence	LE
Mid-urethral synthetic sling inserted by either the transobturator or retropubic route provides equivalent patient-reported outcome at five years.	1a
Mid-urethral synthetic sling inserted by the retropublic routes has higher objective patient-reported cure rates at 8 years.	1b
Long-term analysis of TVT cohorts showed a sustained response up to 17 years.	2b
The transobturator route of insertion is associated with a higher risk of groin pain than the retropubic route.	1a
Long-term analysis showed no difference in terms of efficacy for the skin-to-vagina compared to vagina-to-skin directions up to nine years.	2a
The top-to-bottom direction in the retropubic approach is associated with a higher risk of post-operative voiding dysfunction.	1b
Incontinence surgery has similar outcomes in older patients (≥ 65 years).	2a
Incontinence surgery may be safely performed in obese women, however, outcomes may be inferior.	2b
Improvement in sexual life is higher with single incision slings than with standard MUS.	1a

SUI = stress urinary incontinence; TVT = tension-free vaginal tape.

NB: Most evidence on single-incision slings is from studies using the tension-free vaginal tape secure (TVT-S) device and although this device is no longer available, many women still have the device in place.

4.3.1.4.3 Summary of evidence for open and laparoscopic surgery for stress urinary incontinence

Summary of evidence	LE
Laparoscopic colposuspension has a shorter hospital stay and may be more cost-effective than open colposuspension.	1a

4.3.1.5.3 Summary of evidence for bulking agents

Summary of evidence	LE
Peri-urethral injection of a bulking agent may provide short-term improvement and cure (twelve months), in women with SUI.	1b
Autologous fat and hyaluronic acid as bulking agents have a higher risk of adverse events.	1a
Peri-urethral route of injection of bulking agents may be associated with a higher risk of urinary retention compared to the transurethral route.	2b

SUI = stress urinary incontinence.

4.3.2.1.3 Summary of evidence for colposuspension or sling following failed surgery

Summary of evidence	LE
TVT and TOT have similar outcomes in patients with recurrent SUI.	1a
Burch colposuspension has similar patient reported or objective cure rates when compared to TVT.	1b

TOT = trans-obturator tape; TVT = tension-free vaginal tape.

4.3.3.4 Recommendations for women with both stress urinary incontinence and pelvic organ prolapse

Recommendations for women requiring surgery for bothersome pelvic organ prolapse who have symptomatic or unmasked stress urinary incontinence	Strength rating
Inform women of the increased risk of adverse events with combined surgery compared to prolapse surgery alone, as well as the risk of UI progression if UI is untreated at the time of POP repair.	Strong

POP = pelvic organ prolapse; UI = urinary incontinence.

4.3.5.1.1 Summary of evidence for drug therapy in men with stress urinary incontinence

Summary of evidence	LE
Duloxetine, either alone or combined with conservative treatment, can hasten recovery but does not improve continence rate following prostate surgery. However, it can be associated with significant, albeit often transient, side effects.	1b

4.3.5.3.3 Summary of evidence for fixed male sling

Summary of evidence	LE
There is no evidence that intraoperative placement of an autologous sling during RARP improves return of continence at 6 months.	1b

RARP = robotic assisted radical prostatectomy.

4.3.5.6 Recommendations for men with stress urinary incontinence

Recommendation	Strength rating
Offer duloxetine only to hasten recovery of continence after prostate surgery but inform the patient about the possible adverse events and that its use is off label for this indication in most European countries.	Weak

4.3.6.2.3 Summary of evidence for sacral nerve stimulation

Recommendations	LE
Sacral nerve neuromodulation is not more effective than OnabotulinumA toxin 200 U injection at 6 months.	1b

4.3.6.3.4 Recommendations for cystoplasty/urinary diversion

Recommendations	Strength rating
Offer augmentation cystoplasty to patients with UI who have failed all other treatment options.	Weak
Inform patients undergoing augmentation cystoplasty of the high risk of having to perform clean intermittent self-catheterisation (ensure they are willing and able to do so) and that they need lifelong surveillance.	Weak

UI = urinary incontinence.

2. METHODS

2.1 Introduction

For the 2018 Urinary Incontinence Guidelines, the literature has been assessed for Section 4.3 – Surgical Management. Databases searched included Medline, EMBASE, and the Cochrane Libraries, covering a time frame between January 2012 and March 15th, 2017, Four different PICOS were developed (Slings and tapes, Botox and SNS, Other procedures including Colposuspension and Major surgery), resulting in a total of 2,142 records identified which were retrieved and screened for relevance. Detailed search strategies are available online for each of these PICOS: https://uroweb. org/guideline/urinary-incontinence/?type=appendices-publications.

For the 2018 edition of the EAU Guidelines the Guidelines Office have transitioned to a modified GRADE methodology across all 20 guidelines [6, 7]. For each recommendation within the guidelines there is an accompanying online strength rating form which addresses a number of key elements namely:

1. the overall quality of the evidence which exists for the recommendation, references used in this text are graded according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [8];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact of patient values and preferences on the intervention;
6. the certainty of those patient values and preferences.

These key elements are the basis which panels use to define the strength rating of each recommendation. The strength of each recommendation is represented by the words ‘strong’ or ‘weak’ [9]. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and nature and variability of patient values and preferences. The strength rating forms will be available online.

Additional information can be found in the general Methodology section of this print, and online at the EAU website; http://www.uroweb.org/guideline/.

A list of Associations endorsing the EAU Guidelines can also be viewed online at the above address.

2.2 Review

The Surgical Management section has been peer reviewed prior to publication in 2018. The remainder of the document was peer reviewed prior to publication in 2015. The decision for re-review is made based on the extent of the revision. A major revision resulting in significant changes to the clinical recommendations presented in the text will warrant re-review.

2.3 Future goals

- A systematic review on the topic of female nocturia is ongoing [10].

3. DIAGNOSTIC EVALUATION

3.1 History and physical examination

Taking a careful clinical history is fundamental to the clinical process. Despite the lack of formal evidence, there is universal agreement that taking a history should be the first step in the assessment of anyone with UI. The history should include details of the type, timing and severity of UI, associated voiding and other urinary symptoms. The history should allow UI to be categorised into stress urinary incontinence (SUI), urgency urinary incontinence (UUI) or mixed urinary incontinence (MUI). It should also identify patients who need rapid referral to an appropriate specialist. These include patients with associated pain, haematuria, a history of recurrent urinary tract infection (UTI), pelvic surgery (particularly prostate surgery) or radiotherapy, constant leakage suggesting a fistula, voiding difficulty or suspected neurological disease. In women, an obstetric and gynaecological history may help to understand the underlying cause and identify factors that may impact on treatment decisions. The patient should also be asked about other ill health and for the details of current medications, as these may impact on symptoms of UI.

Similarly, there is little evidence from clinical trials that carrying out a clinical examination improves care, but wide consensus suggests that it remains an essential part of assessment of people with UI. It should include abdominal examination, to detect an enlarged bladder or other abdominal mass, and perineal and digital examination of the rectum (prostate) and/or vagina. Examination of the perineum in women includes an assessment of oestrogen status and a careful assessment of any associated pelvic organ prolapse (POP). A cough test may reveal SUI if the bladder is sufficiently full while pelvic floor contraction together with urethral mobility can be assessed digitally.

3.2 Patient questionnaires

This section includes symptom scores, symptom questionnaires, scales, indexes, patient-reported outcome measures (PROMs) and health-related quality of life (HRQoL) measures. The latter include generic or condition specific measures. Questionnaires should have been validated for the language in which they are being used, and, if used for outcome evaluation, must have been shown to be sensitive to change. The US Food and Drug Administration (FDA) published guidance for industry on patient-reported outcome instruments (questionnaires) in 2009 [11].

*3.2.1 **Questions***

- In patients with UI, can the use of Questionnaires/PROMS differentiate between stress, urgency and mixed incontinence, and does this differentiation impact on quality of life (QoL) after treatment?
- In adults with UI, does assessment using either urinary symptom or QoL questionnaires improve treatment outcome for UI?
- In adults with UI, does assessment of the patient perspective (concerns or expectations) improve patient outcomes, regarding either urinary symptoms or QoL, compared to no patient-reported assessment?

*3.2.2 **Evidence***

Although many studies have investigated the validity and reliability of urinary symptom questionnaires and PROMs most of these studies did not include adult patients diagnosed with UI. This limits the extent to which results and conclusions from these studies can be applied in adults with UI. Some questionnaires (QUID, 3IQ) have potential to discriminate UI types in women [12, 13]. In men ICIQ-UI-SF score does not differentiate UI types [14]. Some questionnaires are responsive to change and may be used to measure outcomes, though evidence on their sensitivity is inconsistent [15-17]. No evidence was found to indicate whether use of QoL or condition specific questionnaires have an impact on outcome of treatment.

Table 1 shows a summary of the ICUD review (2012) with recent additions. Criteria on which questionnaires are assessed include validity, reliability and responsiveness to change.

Table 1: Summary of the ICUD review 2012*.

	Category A (all 3 criteria fulfilled)**	**Category B (2 criteria fulfilled)****	**Category C (only 1 criterion fulfilled)****
Symptom measures and health-related QOL measures	ICIQ-UI Short Form, ICIQFLUTS,ICIQ-MLUTS IIQ and IIQ-7, I-QOL (ICIQ-Uqol), ISS, KHQ, LIS (?-interview), N-QoL, OAB-q SF, OAB-q (ICIQOABqol), PFDI and PFDI-20, PFIQ and PFIQ-7, PRAFAB, UISS	Contilife, EPIQ, LUTS tool IOQ,YIPS	ABSST ISI, ISQ, UIHI, UIQ
Measure of patient satisfaction (patient's measure of treatment satisfaction)	BSW, OAB-S, OABSAT-q, TBS	PPQ	EPI, GPI, PSQ
Goal attainment scales		SAGA	
Screening tools (used to identify patients with UI)	B-SAQ, OAB-SS, OABV8, OAB-V3, QUID	ISQ, USP	3IQ, CLSS, MESA, PUF
Patient symptom scale			
Assessment of symptom bother and overall bother	PPBC, UDI or UDI-6, LUSQ, PGI-I and PGI-S	PFBQ, SSI and SII	PMSES, POSQ, UI-4
Assessment of the impact of urgency	IUSS, U-IIQ, UU Scale, U-UDI	PPIUS, SUIQ, UPScore, UPScale, UQ, USIQ-QOL, USIQ-S, USS	
Questionnaires to assess sexual function and urinary symptoms		FSFI, ICIQ-VS, PISQ, SQoL-F	SFQ
Treatment adherence Measures		MASRI	

** For all abbreviations please see the Abbreviations list in the Appendix at the end of the full Guidelines.*
*** Criteria on which questionnaires are assessed include validity, reliability and responsiveness to change.*

To date, there is no one questionnaire that fulfils all requirements for assessment of people with UI. Clinicians must evaluate the tools which exist, for use alone or in combination, for assessment and monitoring of treatment outcome [18].

The questionnaires can be found on the following websites: www.iciq.net, www.proqolid.org, www.mapi-institute.com, www.pfizerpatientreportedoutcomes.com, www.ncbi.nlm.nih.gov.

3.2.3 Summary of evidence and recommendations for patient questionnaires

Summary of evidence	**LE**
Validated condition specific symptom scores assist in the screening for, and categorisation of, UI.	3
Validated symptom scores measure the severity of UI.	3
Both condition specific and general health status questionnaires measure current health status, and change following treatment.	3

Recommendation	**Strength rating**
Use a validated and appropriate questionnaire when standardised assessment is required (See Table 1, above).	Strong

UI = urinary incontinence.

3.3 Voiding diaries

Measurement of the frequency and severity of lower urinary tract symptoms (LUTS) is an important step in the evaluation and management of lower urinary tract (LUT) dysfunction, including UI. Voiding diaries are a semi-objective method of quantifying symptoms, such as frequency of UI episodes. They also quantify urodynamic variables, such as voided volume and 24-hour or nocturnal total urine volume. Voiding diaries are also known as micturition time charts, frequency/volume charts and bladder diaries.

Discrepancy between diary recordings and the patient rating of symptoms, e.g. frequency or UI, can be useful in patient counselling. In addition, voided volume measurement can be used to support diagnoses, such as overactive bladder (OAB) or polyuria. Diaries can also be used to monitor treatment response and are widely used in clinical trials. In patients with severe UI, a voiding diary is unlikely to accurately report 24-hour urine output and so voided volume may be lower than total bladder capacity.

*3.3.1 **Question***

- In adults with UI, what is the reliability, diagnostic accuracy and predictive value of a voiding diary compared to patient history or symptom score?

*3.3.2 **Evidence***

Two articles have suggested a consensus has been reached in the terminology used in voiding [19, 20]. However, the terms micturition diary, frequency voiding chart and voiding diary, have been used interchangeably for many years and include information on fluid intake, times of voiding, voided volumes, incontinence episodes, pad usage, degree of urgency and degree of UI recorded for at least 24 hours. When reviewing the evidence all possible terminology has been included.

Two studies have demonstrated the reproducibility of voiding diaries in both men and women [21, 22]. Further studies have demonstrated variability of diary data within a 24-hour period and compared voided volumes recorded in diaries with those recorded by uroflowmetry [23, 24]. Another study found that keeping a voiding diary had a therapeutic benefit [25].

A number of observational studies have demonstrated a close correlation between data obtained from voiding diaries and standard symptom evaluation [26-29].

*3.3.3 **Summary of evidence and recommendations for voiding diaries***

Summary of evidence	**LE**
Voiding diaries of three to seven days duration are a reliable tool for the objective measurement of mean voided volume, day time and night time frequency, and incontinence episode frequency.	2b
Voiding diaries are sensitive to change and are a reliable measure of outcome.	2b

Recommendations	**Strength rating**
Ask patients with UI to complete a voiding diary when standardised assessment is needed.	Strong
Use a diary duration of at least three days.	Strong

UI = urinary incontinence.

3.4 Urinalysis and urinary tract infection

Reagent strip ('dipstick') urinalysis may indicate UTI, proteinuria, haematuria or glycosuria requiring further assessment. Refer to the Urological Infections Guidelines for diagnosis and treatment of UTI [30].

*3.4.1 **Question***

- In adults with UI, what is the diagnostic accuracy of urinalysis to detect UTI?
- In adults with UI does treatment of UTI or asymptomatic bacteriuria cure or improve UI compared to no treatment?

*3.4.2 **Evidence***

Urinalysis negative for nitrite and leucocyte esterase reliably excludes UTI in people with UI [31] and should be included, with urine culture when necessary, in the evaluation of all patients with UI. Urinary incontinence may occur during symptomatic UTI [32] and existing UI may worsen during UTI [33]. The rate and severity of UI was unchanged after eradication of asymptomatic bacteriuria in nursing home residents [34].

*3.4.3 **Summary of evidence and recommendations for urinalysis***

Summary of evidence	LE
Urinalysis negative for nitrite and leucocyte esterase reliably excludes UTI.	1
Urinary incontinence may be a symptom during UTI.	3
The presence of a symptomatic UTI worsens symptoms of UI.	3
Elderly nursing home patients with UI do not benefit from treatment of asymptomatic bacteriuria.	2

Recommendations	Strength rating
Perform urinalysis as a part of the initial assessment of a patient with UI.	Strong
If a symptomatic UTI is present with UI, reassess the patient after treatment.	Strong
Do not routinely treat asymptomatic bacteriuria in elderly patients to improve UI.	Strong

UI = urinary incontinence; UTI = urinary tract infection.

3.5 Post-void residual volume

Post-void residual (PVR) volume is the amount of urine that remains in the bladder after voiding. It indicates poor voiding efficiency, which may result from a number of contributing factors. It is important because it may worsen symptoms and, more rarely, may be associated with UTI, upper urinary tract (UUT) dilatation and renal insufficiency. Both bladder outlet obstruction and detrusor underactivity contribute to the development of PVR. Post-void residual can be measured by catheterisation or ultrasound (US). The prevalence of PVR in patients with UI is uncertain, partly because of the lack of a standard definition of an abnormal PVR volume.

*3.5.1 **Question***

In adults with UI, what are the benefits of measuring PVR?

*3.5.2 **Evidence***

Most studies investigating PVR have not included patients with UI. Although some studies have included women with UI and men and women with LUTS, they have also included children and adults with neurogenic UI. In general, the data on PVR can be applied with caution to adults with non-neurogenic UI. The results of studies investigating the best method of measuring PVR [35-40] have led to the consensus that US measurement of PVR is preferable to catheterisation.

In peri- and post-menopausal women without significant LUTS or pelvic organ symptoms, 95% of women had a PVR < 100 mL [41]. In women with UUI, a PVR > 100 mL was found in 10% of cases [42]. Other research has found that a high PVR is associated with pelvic organ prolapse (POP), voiding symptoms and an absence of SUI [41, 43-45].

In women with SUI, the mean PVR was 39 mL measured by catheterisatiovn and 63 mL measured by US, with 16% of women having a PVR > 100 mL [42].

*3.5.3 **Summary of evidence and recommendations for post-void residual***

Summary of evidence	LE
Lower urinary tract symptoms coexisting with UI are associated with a higher rate of PVR compared to asymptomatic subjects.	2

Recommendations	Strength rating
When measuring PVR, use US.	Strong
Measure PVR in patients with UI who have voiding symptoms.	Strong
Measure PVR when assessing patients with complicated UI.	Strong
Post-void residual should be monitored in patients receiving treatments that may cause or worsen voiding dysfunction, including surgery for SUI.	Strong

PVR = post void residual urine; SUI = stress urinary incontinence; UI = urinary incontinence; US = ultrasound.

3.6 Urodynamics

Urodynamic testing is widely used as an adjunct to clinical diagnosis, in the belief that it may help to provide or confirm diagnosis, predict treatment outcome, or facilitate discussion during counselling. For all these reasons,

urodynamics is often performed prior to invasive treatment for UI. These Guidelines will focus on invasive tests, including multichannel cystometry, ambulatory monitoring and video-urodynamics, and different tests of urethral function, such as urethral pressure profilometry, Valsalva leak point pressure estimation, and retrograde urethral resistance measurement.

3.6.1 ***Question***

In adults with UI, what is the reproducibility, diagnostic accuracy and predictive value of urodynamic testing?

3.6.2 ***Evidence***

3.6.2.1 Variability

In common with most physiological tests there is variability in urodynamics results. A number of small studies, assessing same-session repeatability of urodynamic testing, present contradictory findings [46, 47]. Measurement of urethral closure pressure (MUCP) correlates poorly with incontinence severity [48] and there is conflicting evidence about its reproducibility [49, 50]. One method of recording MUCP cannot be compared meaningfully to another [51].

Valsalva leak point pressures are not standardised and there is minimal evidence about reproducibility. Valsalva leak point pressure did not reliably assess incontinence severity in a cohort of women selected for surgical treatment of SUI [52]. The predictive value of the tests, regarding the outcome of treatment, remains unclear. No studies on the reproducibility of ambulatory monitoring were found.

3.6.2.2 Diagnostic accuracy

The diagnostic accuracy of urodynamics is assessed in terms of its correlation with clinical diagnosis of UI and incontinence severity. The problem is that clinical diagnosis and urodynamic findings often do not correlate [53, 54], and normal healthy people may have urodynamic abnormalities.

The diagnostic accuracy of urethral pressure profilometry [48] and 'urethral retro-resistance' is generally poor [55]. Urethral reflectometry may have greater diagnostic accuracy but its clinical role remains unclear [56].

Ambulatory urodynamics may detect unexpected physiological variance from normal more often than conventional cystometry, but the clinical relevance of this is uncertain [57, 58].

3.6.2.3 Question

Does urodynamics influence the outcome of conservative therapy?

3.6.2.4 Evidence

A Cochrane review of seven randomised control trials (RCTs) showed that use of urodynamic tests increased the likelihood of prescribing drugs or avoiding surgery. However, there was no evidence that this influence on decision making altered the clinical outcome of treatment [59]. Subanalysis of an RCT comparing fesoterodine to placebo [60, 61] showed no predictive value for treatment response, by the urodynamic diagnosis of detrusor overactivity (DO).

3.6.2.5 Question

Does urodynamics influence the outcome of surgery for urinary incontinence?

3.6.2.6 Evidence

A high-quality RCT (n = 630) compared office evaluation alone to office evaluation and urodynamics in women with clinical demonstrable SUI about to undergo surgery for SUI. Whilst urodynamics changed the clinical diagnosis in 56% of women [62], there was no difference in levels of UI or any secondary outcome at twelve months follow-up after surgery [63]. Another similar study closed with only 59 women included due to recruitment problems, found that the omission of urodynamics was not inferior in the pre-operative work up of SUI [64]. This study was then redesigned so that patients in whom urodynamics were discordant with clinical assessment (n = 109) were randomly allocated to receive either immediate surgery or individually tailored therapy based on urodynamics. In this trial, performing immediate surgery, irrespective of the result of urodynamics, did not result in inferior outcomes [65].

In observational studies there is no consistent correlation between the result of urethral function tests and subsequent success or failure of SUI surgery [27-30]. The same is true for a secondary analysis of an RCT [66].

Augmentation cystoplasty is only performed in patients with a urodynamic diagnosis of DO, so no statement can be made about predictive value for this group [61].

The Panel recognise that it may be valuable to use urodynamic test results to select the optimum surgical procedure but, at the time of this review, there is inconsistent evidence regarding any predictive value that would support this approach.

3.6.2.7 Question

Does urodynamics help to predict complications of surgery for UI?

3.6.2.8 Evidence

There have been no RCTs designed to answer this question.

The presence of pre-operative DO has been associated with post-operative UUI, but did not predict overall treatment failure following mid-urethral sling [66] or following sling surgery or colposuspension.

Whilst low pre-operative flow rate has been shown to correlate with post-operative voiding dysfunction [67, 68], *post-hoc* analysis of two high-quality surgical trials showed that no pre-operative urodynamic parameter had the ability to predict post-operative voiding dysfunction in a selected population of women with low pre-operative PVR [69, 70].

3.6.2.9 Question

Does urodynamics influence the outcome of treatment for post-prostatectomy urinary incontinence in men?

3.6.2.10 Evidence

There are no RCTs examining the clinical usefulness of urodynamics in post-prostatectomy UI. Whilst urodynamics will distinguish causes of incontinence, its ability to predict outcome of surgery for incontinence for these men is uncertain [71, 72].

*3.6.3 **Summary of evidence and recommendations for urodynamics***

Summary of evidence	**LE**
Most urodynamic parameters show variability within the same session and over time, and this limits their clinical usefulness.	3
Different techniques of measuring urethral function may have good test-retest reliability, but do not consistently correlate to other urodynamic tests or to the severity of UI.	3
There is limited evidence that ambulatory urodynamics is more sensitive than conventional urodynamics for diagnosing SUI or DO.	2
There may be inconsistency between history and urodynamic results.	3
Preliminary urodynamics can influence the choice of treatment for UI, but does not affect the outcome of conservative therapy or drug therapy for SUI.	1a
Pre-operative urodynamics in women with uncomplicated, clinically demonstrable, SUI does not improve the outcome of surgery for SUI.	1b
There is no consistent correlation between the result of urethral function tests and subsequent success or failure of SUI surgery.	3
There is no consistent evidence that pre-operative DO is associated with surgical failure of MUS in women.	3
The presence of pre-operative DO may be associated with persistence of urgency post-operatively.	3
There is no evidence that urodynamics predicts the outcomes of treatment for post-prostatectomy incontinence in men.	4

Recommendations *(NB: Concerning only neurologically intact adults with UI)*	**Strength rating**
When performing urodynamics in patients with UI adhere to 'Good Urodynamic Practice' standards as described by the International Continence Society [73]: • attempt to replicate the patient's symptoms; • check recordings for quality control; • interpret results in the context of the clinical problem; • remember there may be physiological variability within the same individual.	Strong
Do not routinely carry out urodynamics when offering treatment for uncomplicated SUI.	Strong

Perform urodynamics if the findings may change the choice of invasive treatment.	Weak
Do not use urethral pressure profilometry or leak point pressure to grade severity of incontinence.	Strong

DO = detrusor overactivity; MUS = mid-urethral sling; SUI = stress urinary incontinence; UI = urinary incontinence.

*3.6.4 **Research priority***

Does any individual urodynamic test, or combination of tests, influence the choice of treatments or prediction of treatment outcome for UI?

3.7 Pad testing

Measurement of urine loss using an absorbent pad worn over a set period of time or during a protocol of physical exercise can be used to quantify the presence and severity of UI, as well as a patient's response to treatment.

*3.7.1 **Questions***

- In adults with UI, what is the reliability, diagnostic accuracy and predictive value of pad testing?
- In adults with UI, is one type of pad test better than another?

*3.7.2 **Evidence***

The clinical usefulness of pad tests for people with UI has been assessed in two SRs [74, 75]. A one-hour pad test using a standardised exercise protocol and a diagnostic threshold of 1.4 g shows good specificity but lower sensitivity for symptoms of SUI and MUI. A 24-hour pad test using a threshold of 4.4 g is more reproducible but is difficult to standardise with variation according to activity level [76]. Pad test with a specific short graded exercise protocol also has diagnostic value but a negative test should be repeated or the degree of provocation increased [77]. The usefulness of pad tests in quantifying severity and predicting outcome of treatment is uncertain [74, 78] although early post-operative testing may predict future continence in men after prostatectomy [79]. Pad test is responsive to change following successful treatment [80]. There is no evidence that one type of pad test is superior to another.

*3.7.3 **Summary of evidence and recommendations for pad testing***

Summary of evidence	**LE**
A pad test can diagnose UI accurately.	2
Standardisation of bladder volume and degree of provocation improves reproducibility.	2
Twenty-four hours is sufficient duration for home-based testing balancing diagnostic accuracy and adherence.	2
Change in leaked urine volume on pad tests can be used to measure treatment outcome.	2

Recommendations	**Strength rating**
Use a pad test of standardised duration and activity protocol.	Strong
Use a pad test when quantification of UI is required.	Weak

UI = urinary incontinence.

*3.7.4 **Research priority***

- Do the results of pad testing influence the choice of treatments or the prediction of the outcome of treatment for UI?
- Does the amount of physical activity influence the outcome of 24-hour pad testing leading to overestimation of the severity of UI?

3.8 Imaging

Imaging improves our understanding of the anatomical and functional abnormalities that may cause UI. In clinical research, imaging is used to understand the relationship between anatomy and function, between conditions of the central nervous system (CNS) or of the LUT and UI, and to investigate the relationship between LUT and pelvic floor imaging and treatment outcome.

Ultrasound and magnetic resonance imaging (MRI) have largely replaced X-ray imaging. Ultrasound is preferred to MRI because of its ability to produce three-dimensional and four-dimensional (dynamic) images at lower cost and wider availability. Studies on LUT imaging in patients with UI often include an evaluation of surgical outcomes, making design and conduct of these trials challenging.

*3.8.1 **Questions***

In adults with UI:

- What is the reliability and accuracy of imaging in the diagnosis of UI?
- Do the results of imaging influence the choice of treatment for UI?
- Do the results of imaging help predict outcome of treatment for UI?
- Do the results of imaging help evaluate outcome of treatments for UI?

*3.8.2 **Evidence***

Many studies have evaluated the imaging of bladder neck mobility by US and MRI, and concluded that UI cannot be identified by a particular pattern of urethrovesical movements [81]. In addition, the generalised increase in urethral mobility after childbirth does not appear to be associated with *de novo* SUI [82].

There is a general consensus that MRI provides good global pelvic floor assessment, including pelvic organ prolapse (POP), defecatory function and integrity of the pelvic floor support [83]. However, there is a large variation in MRI interpretation between observers [84] and little evidence to support its clinical usefulness in the management of UI. Studies have assessed the use of imaging to assess the mechanism of mid-urethral sling (MUS) insertion for SUI. One study suggested that MUS placement decreased mobility of the mid-urethra but not mobility of the bladder neck [85]. Following MUS, a wider gap between symphysis and sling (assessed by imaging) has been shown to correlate with a lower chance of cure of SUI [86].

Several imaging studies have investigated the relationship between sphincter volume and function in women [87] and between sphincter volume and surgery outcome, in men and women [88, 89]. In patients undergoing radical prostatectomy, longer membranous urethra before and after surgery was associated with a higher rate of continence [90]. However, no imaging test has been shown to predict the outcome of treatment for UI. Imaging of the pelvic floor can identify *levator ani* detachment and hiatus size, although there is little evidence of a relationship to clinical benefit after treatment of UI.

Detrusor wall thickness

As OAB has been linked to DO, it has been hypothesised that frequent detrusor contractions may increase detrusor/bladder wall thickness (DWT/BWT). However, there is no evidence that BWT/DWT imaging improves management of OAB in practice. No consensus exists as to the relationship between OAB and increased BWT/DWT [91].

*3.8.3 **Summary of evidence and recommendations for imaging***

Summary of evidence	**LE**
Imaging can reliably be used to measure bladder neck and urethral mobility, although there is no evidence of clinical benefit for patients with UI.	2b
There is no consistent evidence that bladder (detrusor) wall thickness measurement is useful in the management of UI.	3

Recommendation	**Strength rating**
Do not routinely carry out imaging of the upper or lower urinary tract as part of the assessment of UI.	Strong

UI = urinary incontinence.

*3.8.4 **Research priority***

More research is needed into the relationship between sling position, as determined by imaging, and surgical outcome.

4. DISEASE MANAGEMENT

4.1 Conservative management

In clinical practice, it is the convention that non-surgical therapies are tried first because they usually carry the least risk of harm. They are often used in combination which makes it difficult to determine which components are effective. Containment devices play an important role, especially for individuals who prefer to avoid the risks of interventional treatments, or in whom active treatment is impossible for any reason.

*4.1.1 **Simple clinical interventions***

4.1.1.1 Underlying disease/cognitive impairment

Urinary incontinence, especially in the elderly, has been associated with multiple comorbid conditions including:

- cardiac failure;
- chronic renal failure;
- diabetes;
- chronic obstructive pulmonary disease;
- neurological disease including stroke and multiple sclerosis;
- general cognitive impairment;
- sleep disturbances, e.g. sleep apnoea;
- depression;
- metabolic syndrome.

It is possible that improvement of associated disease may reduce the severity of urinary symptoms. However, this is often difficult to assess as patients frequently suffer from more than one condition. In addition, interventions may be combined and individualised, making it impossible to decide which alteration in an underlying disease has affected a patient's UI.

4.1.1.1.1 Question

In adults with UI, does improving an associated condition improve UI compared to no correction of that condition?

4.1.1.1.2 Evidence

There is compelling evidence that there is a higher prevalence of UI in women with type 2 diabetes. One study showed no correlation between earlier intensive treatment of type 1 diabetes mellitus and the prevalence of UI in later life vs. conventional treatment [92].

4.1.1.1.3 Summary of evidence and recommendations regarding associated conditions

Summary of evidence	**LE**
There is a lack of evidence that improving any associated condition improves UI, with the exception of weight loss (see section 4.1.2.4 Obesity and weight loss).	3

Recommendation	**Strength rating**
Patients with UI who have associated conditions, should have appropriate treatment for those conditions in line with good medical practice.	Strong

UI = urinary incontinence.

4.1.1.2 Adjustment of other (non-incontinence) medication

Although UI is listed as an adverse effect of many drugs in drug compendia, this mainly results from uncontrolled individual patient reports and post-marketing surveillance. Few controlled studies have used the occurrence of UI as a primary outcome, or were powered to assess the occurrence of statistically significant UI, or worsening rates against placebo. In most cases, it is therefore not possible to be sure that a drug causes UI.

In patients with existing UI, particularly the elderly, it may be difficult or impossible to distinguish between the effects of medication, comorbidity or ageing on UI. Although changing drug regimens for underlying disease may be considered as a possible early intervention for UI, there is very little evidence of benefit [53]. There is also a risk that stopping or altering medication may result in more harm than benefit.

4.1.1.2.1 Question

In adults with UI, does adjustment of other (non-incontinence) medication improve UI compared to no change in treatment?

4.1.1.2.2 Evidence

Structured literature review failed to identify any studies addressing whether adjustment of specific medications could alter existing symptoms of UI. Also, there is little evidence relating to the occurrence or worsening of UI in relation to prescription of any specific drugs.

4.1.1.2.3 Summary of evidence and recommendations for adjustment of other (non-incontinence) medication

Summary of evidence	**LE**
There is very little evidence that alteration of non-incontinence medication can cure or improve symptoms of UI.	3

Recommendations	**Strength rating**
Take a history of current medication use from all patients with UI.	Strong
Review any new medication associated with the development or worsening of UI.	Weak

UI = urinary incontinence.

4.1.1.3 Constipation

Several studies have shown strong associations between constipation and UI. Constipation can be improved by behavioural, physical and medical treatments.

4.1.1.3.1 Question

Does treatment for constipation improve UI?

4.1.1.3.2 Evidence

Two, large, cross-sectional population-based studies [93, 94] and two longitudinal studies [95, 96] showed that constipation was a risk factor for LUTS. An observational study comparing women with UI and women with POP to controls found that a history of constipation was associated with both prolapse and UI [97]. One RCT found that a multimodal intervention in elderly patients, involving assisted toileting, fluid intake, etc., reduced the occurrence of UI and constipation, while behavioural therapy appeared to improve both [98].

In conclusion, constipation appears to be associated with UI. However, there is no evidence to show whether or not treating constipation improves UI, although both constipation and UI appear to be improved by certain behavioural interventions.

4.1.1.3.3 Summary of evidence and recommendations for constipation

Summary of evidence	**LE**
There is a consistent association between a history of constipation and the development of UI and POP.	3
There is no consistent evidence in adults that treatment of constipation alone improves UI.	4

Recommendation	**Strength rating**
Adults with UI who also suffer from constipation should be given advice about bowel management in line with good medical practice.	Strong

POP = pelvic organ prolapse; UI = urinary incontinence.

4.1.1.3.4 Research priority

Does the normalisation of bowel habit improve UI in patients who are constipated?

4.1.1.4 Containment

Containment is important for people with UI when active treatment does not cure the problem, or when it is not available or not possible. Some individuals may prefer containment rather than undergo active treatment with

its associated risks. This includes the use of absorbent pads, urinary catheters, external collection devices, penile clamps for men and intravaginal devices for women. Studies of catheter use are not specific to patients with non-neurogenic UI. Detailed literature summaries can be found in the current ICUD monograph [1] and in European Association of Urological Nurses guidance documents [99-101]. A useful resource for health care professionals and patients can be found at: www.continenceproductadvisor.org.

4.1.1.4.1 Question
For adults with UI, is one type of containment device better than another?

4.1.1.4.2 Evidence
One RCT involving elderly women in care comparing management with pads to indwelling urethral catheter found no difference in dependency level or skin integrity score at six months [102]. Use of an external sheath was compared with indwelling catheterisation over 30 days in an RCT involving elderly men resident in hospital [103]; there were no differences in bacteriuria or symptomatic UTI but the sheath was more comfortable. A short-term (two weeks) crossover RCT in men with UI found that disease specific QoL was better when using an external sheath and more men preferred it, compared to pads [104].

4.1.1.4.3 Question
For men or women with UI, is one type of pad better than another?

4.1.1.4.4 Evidence
A SR of six RCTs comparing different types of pads found that pads filled with superabsorbent material were better than standard pads, whilst evidence that disposable pads were better than washable pads was inconsistent [105]. For men with light UI, a randomised crossover trial found that a leaf-shaped type of pad was preferred to rectangular pads [106]. A series of three crossover RCTs examined performance of different pad designs for differing populations [107]. For women with light UI, disposable insert pads (within washable pouch pants) were most effective. In adults with moderate/severe incontinence, disposable pull-up pants were more effective for women, whilst for men disposable diapers were more effective during the day and washable diapers at night.

4.1.1.4.5 Question
For men or women with UI, is one type of catheter or external collection device better than another?

4.1.1.4.6 Evidence
A Cochrane review summarised three RCTs comparing different types of long-term indwelling catheters and found no evidence that one catheter material or type of catheter was superior to another [108]. A SR of non-randomised studies found no differences in UTI outcome or UUT changes between use of suprapubic or urethral catheter drainage; however, patients with suprapubic catheters were less likely to have urethral complications [109]. For people using intermittent catheterisation, a Cochrane review found no evidence that one type of catheter or regimen of catheterisation was better than another [110]. However, there is recent evidence from a narrative review suggesting that in certain populations using single-use catheters may reduce urethral trauma and UTI [111]. A Cochrane review summarising five trials comparing washout policies in adults with indwelling urinary catheters found inconsistent evidence of benefit [112].

A further Cochrane review summarising eight trials testing whether antibiotic prophylaxis was beneficial for adults using intermittent or indwelling catheterisation found it reduced incidence of symptomatic UTI but possible harms were not assessed [113].

4.1.1.4.7 Question
For men and women with UI, are external pressure devices more effective than standard treatment and is one device better than another?

4.1.1.4.8 Evidence
A crossover RCT in twelve men with post-prostatectomy incontinence found a hinge-type penile clamp to be more effective than circular clamps for control of UI and that the hinge-type penile clamp was preferred by participants, although it reduced penile blood flow [114].

A Cochrane review summarised seven trials comparing mechanical devices in women with UI finding limited evidence that SUI was reduced by intravaginal devices, no evidence on the effectiveness of intra-urethral devices, and that there was no difference in control of UI between intravaginal and intra-urethral devices [115].

There was no difference in outcome at twelve months in women with SUI between vaginal pessary alone; pelvic floor muscle training (PFMT) alone; and vaginal pessary + PFMT, although vaginal pessary was inferior to PFMT at three months for bother from UI.

4.1.1.4.9 Summary of evidence and recommendations for containment

Summary of evidence	**LE**
Pads are effective in containing urine.	1b
Hinge-type penile clamps are more effective than circular clamps to control SUI in men.	2a
Vaginal devices may improve SUI in women in selective groups.	2a

Recommendations	**Strength rating**
Ensure that adults with UI and/or their carers are informed regarding available treatment options before deciding on containment alone.	Strong
Offer incontinence pads and/or containment devices for management of UI.	Strong

SUI = stress urinary incontinence; UI = urinary incontinence.

4.1.1.4.10 Research priority

To develop methods for assessing the best method of containment for individual adults with UI.

*4.1.2 **Lifestyle interventions***

Examples of lifestyle factors that may be associated with incontinence include obesity, smoking, level of physical activity and diet. Modification of these factors may improve UI.

4.1.2.1 Caffeine reduction

Many drinks contain caffeine, particularly tea, coffee and cola. Anecdotal evidence of urinary symptoms being aggravated by excessive caffeine intake has focused attention on whether caffeine reduction may improve UI. However, a cross-sectional population survey found no statistical association between caffeine intake and UI [116]. Lack of knowledge about the caffeine content of different drinks has made the role of caffeine reduction in alleviating UI difficult to assess.

4.1.2.1.1 Question

In adults with UI, does caffeine reduction improve UI or QoL compared to no caffeine reduction?

4.1.2.1.2 Evidence

Four studies were found on the effect of caffeine reduction on UI [117-120]. They were of moderate quality and the results were inconsistent. The studies were mainly in women, so results can only be cautiously generalised to men [118, 119]. One RCT showed that reducing caffeine intake as an adjunct to behavioural therapy resulted in reduced urgency but not reduced UI compared to behavioural therapy alone [118]. Another RCT found that reducing caffeine had no benefit for UI [119]. A further interventional study in the elderly showed borderline significance for the benefit of reducing caffeine intake on UI [120]. In a large prospective cohort study there was no evidence that caffeine reduction reduced the risk of progression of UI over two years [121].

4.1.2.1.3 Sumary of evidence for caffeine reduction

Summary of evidence	**LE**
Reduction of caffeine intake does not improve UI.	2
Reduction in caffeine intake may improve symptoms of urgency and frequency.	2

UI = urinary incontinence.

4.1.2.2 Physical exercise

Regular physical activity may strengthen the pelvic floor musculature and possibly decrease the risk of developing UI, especially SUI. However, it is also possible that heavy physical exercise may aggravate UI.

4.1.2.2.1 Question

Does physical exercise cause, improve or exacerbate UI in adults?

4.1.2.2.2 Evidence

The association between exercise and UI is unclear. Four studies [116, 122-124] in differing populations concluded that strenuous physical exercise increases the risk of SUI during periods of physical activity. There is also consistent evidence that physically active females and elite athletes experience higher levels of SUI than control populations [125-130]. On the other hand, the presence of UI may prevent women from taking exercise [131]. There is no evidence that strenuous exercise predisposes athletes to the development of SUI later in life [132]. Lower levels of UI have been observed in cohorts of women who undertake moderate exercise, but it remains unclear whether taking exercise can prevent development of UI [133, 134].

4.1.2.2.2.1 The elderly

Three RCTs in the elderly confirmed that exercise, as a component of a multidimensional regime including PFMT and weight loss, was effective in improving UI in women. It is not clear which component of such a scheme is most important [98, 135, 136].

4.1.2.2.3 Summary of evidence for physical excercise

Summary of evidence	**LE**
Female athletes may experience UI during intense physical activity but not during common activities.	3
Strenuous physical activity does not predispose for women to UI later in life.	3
Moderate exercise is associated with lower rates of UI in middle-aged or older women.	2b

UI = urinary incontinence.

4.1.2.3 Fluid intake

Modification of fluid intake, particularly restriction, is a strategy commonly used by people with UI to relieve symptoms. Advice on fluid intake given by healthcare professionals should be based on 24-hour fluid intake and urine output measurements. From a general health point of view, it should be advised that fluid intake should be sufficient to avoid thirst and that low or high 24-hour urine output should be investigated.

4.1.2.3.1 Question

In adults with UI, what is the effect of modifying fluid intake compared to not modifying fluid intake on symptoms and QoL?

4.1.2.3.2 Evidence

The few RCTs [119, 137, 138] provide inconsistent evidence. In most studies, the instructions for fluid intake were individualised and it is difficult to assess participant adherence to protocol. All available studies were in women. An RCT [138] showed that a reduction in fluid intake by 25% improved symptoms in patients with OAB but not UI. Personalised fluid advice compared to generic advice made no difference to continence outcomes in people receiving antimuscarinics for OAB, according to an RCT comparing drug therapy alone to drug therapy with behavioural advice [139].

4.1.2.3.3 Summary of evidence for fluid intake

Summary of evidence	**LE**
There is conflicting evidence on whether fluid modification improves UI.	2

UI = urinary incontinence.

4.1.2.4 Obesity and weight loss

Being overweight or obese has been identified as a risk factor for UI in many epidemiological studies [140, 141]. There is evidence that the prevalence of both UUI and SUI increases proportionately with rising body mass index [142]. The proportion of patients who undergo surgery for incontinence who are overweight or obese is higher than that of the general population [143].

4.1.2.4.1 Question

In adults with UI, does weight loss lead to an improvement in symptoms of UI or QoL?

4.1.2.4.2 Evidence

All the available evidence relates to women. Three SRs plus two large RCTs concluded that weight loss was beneficial in improving UI [140, 141, 144]. Five further RCTs reported a similar beneficial effect on incontinence

following surgical weight reduction programmes [145-149]. Two large studies in women with diabetes, for whom weight loss was the main lifestyle intervention, showed UI did not improve but there was a lower subsequent incidence of UI among those who lost weight [145, 150]. There have been other cohort studies and case-control studies suggesting similar effects, including surgery for the morbidly obese [151-155].

4.1.2.4.3 Summary of evidence for obesity and weight loss

Summary of evidence	LE
Obesity is a risk factor for UI in women.	1b
Non-surgical weight loss in overweight and obese women improves UI.	1a
Surgical weight loss improves UI in obese women.	1b
Weight loss in obese women improves UI.	1b
Weight loss in obese adults with diabetes mellitus reduces the risk of developing UI.	1b

UI = urinary incontinence.

4.1.2.5 Smoking

Smoking cessation is now a generalised public health measure and has been shown to be weakly associated with improving urgency frequency and UI [116, 156].

4.1.2.5.1 Question

In adults with UI, does smoking cessation improve patient outcomes regarding either urinary symptoms or QoL compared to continued smoking?

4.1.2.5.2 Evidence

The effect of smoking cessation on UI was described as uncertain in a NIHR review [157].

4.1.2.5.3 Summary of evidence for smoking cessation

Summary of evidence	LE
There is no evidence that smoking cessation will improve the symptoms of UI.	4

UI = urinary incontinence.

4.1.2.6 Recommendations for lifestyle interventions

Recommendations	Strength rating
Encourage overweight and obese adults with UI to lose weight and maintain weight loss.	Strong
Advise adults with UI that reducing caffeine intake may improve symptoms of urgency and frequency but not incontinence.	Strong
Review type and amount of fluid intake in patients with UI.	Weak
Provide smoking cessation strategies to patients with UI who smoke.	Strong

UI = urinary incontinence.

4.1.2.7 Research priority

Which lifestyle modifications are effective for the cure or sustained improvement of UI?

4.1.3 ***Behavioural and Physical therapies***

Terminology relating to behavioural and physical therapies remains confusing because of the wide variety of ways in which treatment regimens and combinations of treatments have been delivered in different studies [158]. The terms are used to encompass all treatments which require a form of self-motivated personal retraining by the patient and also include techniques which are used to augment this effect.

Approaches include bladder training (BT) and PFMT, but terms such as bladder drill, bladder discipline and bladder re-education and behaviour modification are also used. Almost always in clinical practice, these will be introduced as part of a package of care including lifestyle changes, patient education and possibly some cognitive therapy as well. The extent to which individual therapists motivate, supervise and monitor these interventions is likely to vary but it is recognised that these influences are important components of the whole treatment package.

4.1.3.1 Prompted voiding

The term 'prompted voiding' implies that carers, rather than the patient, initiate the decision to void and this applies largely to an assisted care setting.

Two SRs (nine RCTs) [159, 160] confirmed a positive effect on continence outcomes for prompted voiding in comparison to standard care [160]. Timed voiding is defined as fixed, pre-determined, time intervals between toileting, applicable for those with or without cognitive impairment. A Cochrane review of timed voiding reviewed two RCTs, finding inconsistent improvement in continence compared with standard care in cognitively impaired adults [161].

4.1.3.2 Bladder Training

A programme of patient education along with a scheduled voiding regimen with gradually adjusted voiding intervals. Specific goals are to correct faulty habit patterns of frequent urination, improve control over bladder urgency, prolong voiding intervals, increase bladder capacity, reduce incontinent episodes and restore patient confidence in controlling bladder function. The ideal form or intensity of a BT programme for UI is unclear. It is also unclear whether or not BT can prevent the development of UI.

4.1.3.2.1 Questions

In adults with UI:

- Is BT better than no treatment for cure or improvement of UI?
- Is BT better than other conservative treatments for cure or improvement of UI?
- Does BT, as an adjunct to other conservative treatments, cure or improve UI?
- Are the benefits of BT durable in the longer term?
- Are there any patient groups for whom BT is more effective?

4.1.3.2.2 Evidence

There have been three SRs on the effect of BT compared to standard care [53, 157, 162] confirming that BT is more effective than no treatment in improving UUI. The addition of BT to anticholinergic therapy did not improve UI compared to antimuscarinics alone but it did improve frequency and nocturia [163].

This review identified seven RCTs in which BT was compared to drug therapy alone and showed only a benefit for oxybutynin in cure and improvement of UI [163].

Bladder training alone is inferior to a high-intensity programme of PFMT to improve SUI in elderly women [164]. Bladder training is better than intravaginal pessaries to control SUI, although the improvement may only be short term. Whatever the method of training used, any benefit of BT on UI is likely to be of short duration unless the BT programme is practised repeatedly. No adverse events have been reported with BT. Biofeedback combined with BT increased continence rates and improved MUI in two RCTs [162].

4.1.3.2.3 Summary of evidence for bladder training

Summary of evidence	**LE**
Bladder training is effective for improvement of UI in women.	1b
The effectiveness of BT diminishes after the treatment has ceased.	2
The comparative benefit of BT and drugs for the improvement of UUI remains uncertain.	2
The combination of BT with antimuscarinic drugs does not result in greater improvement of UI but may improve frequency and nocturia.	1b
Bladder training is better than pessary alone.	1b
Prompted voiding, either alone or as part of a behavioural modification programme, improves continence in elderly, care-dependent people.	1b

BT = bladder training; UI = urinary incontinence; UUI = urgency urinary incontinence.

For recommendations see section 4.1.3.5.

4.1.3.3 Pelvic floor muscle training (PFMT)

Pelvic floor muscle training is used to improve function of the pelvic floor, improving urethral stability. There is some evidence that improving pelvic floor function may inhibit bladder contraction in patients with OAB [165]. Pelvic floor muscle training may be used to prevent UI, e.g. in childbearing women before birth, in men about

to undergo radical prostatectomy, or as part of a planned recovery programme after childbirth or surgery. Most often, PFMT is used to treat existing UI, and may be augmented with biofeedback (using visual, tactile or auditory stimuli), surface electrical stimulation (ES) or vaginal cones.

4.1.3.3.1 Question

In adult men and women suffering from UI, does treatment with PFMT, given either alone or augmented with biofeedback, ES or vaginal cones, improve or cure UI or improve QoL, compared to no treatment, sham treatment or other conservative treatments, e.g. bladder training, ES or vaginal cones?

4.1.3.3.2 Evidence

In a recent UK Health Technology Appraisal (HTA), the role of PFMT in the care of women with SUI was analysed in a direct comparison of treatments using a mixed treatment comparison model, which compared different 'packages' of care [157]. This extensive meta-analysis reviewed data from 37 interventions and 68 direct comparisons, while the mixed treatment comparisons examined combinations of fourteen different types of intervention from 55 separate trials. The mixed treatment comparison used both indirect and direct comparisons and may provide more accurate estimates of effect. Where relevant, the Health Technology Appraisal has influenced the evidence and recommendations in these Guidelines. The Agency for Healthcare Research and Quality (AHRQ) review of nonsurgical treatment of UI in adult women also included indirect comparison methods as well as conventional meta-analysis [162].

4.1.3.3.3 Efficacy of PFMT in SUI, UUI and MUI in women

This question has been addressed by several SRs [157, 162, 166], all report inconsistency between studies because of poor reporting of technique and different outcome measures. Meta-analysis showed that PFMT was effective for cure or improvement of incontinence, and improvement in QoL. The effect applies in women with SUI, UUI and MUI though the effect in MUI is lower than in women with pure SUI. A Cochrane review comparing different approaches to delivery of PFMT (21 RCTs) concluded that increased intensity of delivery of the therapy improves response and that there is no consistent difference between group therapy and individualised treatment sessions [167]. No other consistent differences between techniques were found.

With regard to the durability of PFMT, another RCT reported fifteen-year follow-up outcomes of an earlier RCT, showing that long-term adherence to treatment was poor and half of patients had progressed to surgery [168]. Numerous SRs have addressed the question of whether the effects of PFMT and BT are additive [157, 162, 169]. These reviews are confounded by differences in patient selection and have arrived at conflicting conclusions leaving uncertainty about the extent to which one treatment may augment the other. Similarly, there remains uncertainty about the additional value of biofeedback with SRs reaching differing conclusions [162, 169].

Comparison of PFMT to other treatments was extensively reviewed by both AHRQ and the 2010 UK HTA [157, 162], which considered additional non-randomised data as part of a mixed treatment comparison. The UK HTA resulted in a number of different findings from those based solely on direct comparisons. In conclusion, the HTA, using a revised methodology, supporting the general principle that greater efficacy was achieved by adding together different types of treatment and by increasing intensity.

Efficacy of PFMT in childbearing women

Two SRs [170, 171] reviewed RCTs in pregnant or postpartum women, which included PFMT in one arm of the trial. Treatment of UI with PFMT in the postpartum period increased the chances of continence at 12 months' postpartum.

4.1.3.3.4 PFMT in the elderly

The effect of PFMT in women with SUI does not seem to decrease with increased age: in trials with older women with SUI it appeared both primary and secondary outcome measures were comparable to those in trials focused on younger women [135, 164, 172].

4.1.3.3.5 PFMT in men (post radical prostatectomy)

A 2015 Cochrane review concluded that there was no overall benefit at twelve months post-surgery for men who received post-operative PFMT for the treatment of post-prostatectomy urinary incontinence (PPI) and that the benefits of conservative treatment of PPI remain uncertain [173]. A meta-analysis within this review showed that a greater proportion of men were dry from between three and twelve months suggesting that PFMT may speed recovery of continence. A subsequent study adds to this evidence [174].

Two additional RCTs have shown that written instructions alone offer similar levels of improvement to supervised PFMT [175, 176]. One RCT found that PFMT was helpful in men who had been incontinent for at least one year after prostatectomy, and who had had no previous therapy [177].

One RCT compared PFMT to no treatment in men undergoing trans-urethral resection of the prostate (TURP). There was no demonstrable difference in the incidence of post-operative incontinence up to twelve months [178].

4.1.3.3.6 Summary of evidence for pelvic floor muscle training

Summary of evidence	**LE**
Pelvic floor muscle training (PFMT) for women with UI	
Pelvic floor muscle training is better than no treatment for improving UI and QoL in women with SUI and MUI.	1
Higher-intensity, supervised treatment regimes, and the addition of biofeedback, confer greater benefit in women receiving PFMT.	1
Short-term benefits of intensive PFMT are not maintained at fifteen-year follow-up.	2
Pelvic floor muscle training commencing in the early postpartum period improves UI in women for up to twelve months.	1
Pelvic floor muscle training for post-prostatectomy UI	
Pelvic floor muscle training appears to speed the recovery of continence following radical prostatectomy.	1b
Pelvic floor muscle training does not cure UI in men post radical prostatectomy or transurethral prostatectomy.	1b
There is conflicting evidence on whether the addition of bladder training, ES or biofeedback increases the effectiveness of PFMT alone.	2
Pre-operative PFMT does not confer additional benefit to men undergoing radical prostatectomy.	1b

ES = electrical stimulation; MUI = mixed urinary incontinence; PFMT = pelvic floor muscle training; QoL=quality of life; SUI = stress urinary incontinence; UI = urinary incontinence.

For recommendations see section 4.1.3.5.

4.1.3.3.7 Electrical stimulation

The details and methods of delivery of ES vary considerably. Electrical stimulation of the pelvic floor can also be combined with other forms of conservative therapy, e.g. PFMT and biofeedback. Electrical stimulation is often used to assist women who cannot initiate contractions to identify their pelvic floor muscles. Electrical stimulation is also used in patients with OAB and UUI, for detrusor inhibition. It has been suggested that ES probably targets the pelvic floor directly in SUI and the detrusor muscle or pelvic floor muscle or afferent innervation in UUI.

4.1.3.3.8 Question

In adults with UI, does treatment with ES improve or cure symptoms of UI or QoL compared to no/sham treatment or antimuscarinics?

4.1.3.3.9 Evidence

Most evidence on ES refers to women with SUI. The topic has been included in two HTAs [157, 162] and three SRs [53, 179, 180]. The reviews include analysis of fifteen trials and use different comparison methods, but differ in their assessment of whether ES is more effective than sham stimulation and whether ES adds to the benefit of PFMT alone. Studies were considered to be of generally low quality, with a variety of stimulation parameters, treatment regimens and outcome parameters [173].

A subanalysis in a SR on one small low quality RCT in which ES had been compared to oxybutynin and PFMT in patients with UI, showed no difference in incontinence outcomes [181].

A Cochrane review of ES in men with UI (six RCTs) concluded that there was some evidence that ES enhanced the effect of PFMT in the short-term but not after six months. Electrical Stimulation was also more effective than sham stimulation at six, but not twelve months. There were, however, more adverse effects (pain or discomfort) with ES [182].

Electromagnetic stimulation has been promoted as treatment for UI but weak evidence of the short-term and long-term effects has been found in SRs [183, 184].

4.1.3.3.10 Summary of evidence for electrical stimulation

Summary of evidence	LE
In adults with UI, ES may improve UI compared to sham treatment and antimuscarinics.	2
Electrical stimulation may add benefit to PFMT in the short-term.	2

ES = electrical stimulation, PFMT = pelvic floor muscle training; UI = urinary incontinence.

For recommendations see section 4.1.3.5.

4.1.3.4 Posterior tibial nerve stimulation

Electrical stimulation of the posterior tibial nerve (PTNS) delivers electrical stimuli to the sacral micturition centre via the S2-S4 sacral nerve plexus. Stimulation is done percutaneously with a fine, 34-G, needle, inserted just above the medial aspect of the ankle (P-PTNS). Transcutaneous stimulation is also available (T-PTNS). Treatment cycles typically consist of twelve weekly treatments of 30 minutes.

4.1.3.4.1 Question

In adults suffering from UUI, what is the clinical effectiveness of PTNS compared to sham treatment or alternative treatment such as antimuscarinic drugs?

4.1.3.4.2 Evidence

P-PTNS

The reviewed studies included two twelve-week RCTs of PTNS against sham treatment [185, 186], one comparing PTNS to tolterodine, and a three-year extension trial utilising a maintenance protocol in patients with UUI [187, 188]. The results of studies of PTNS in women with refractory UUI are consistent. Considered together, these results suggest that PTNS improves UUI in women who did not have adequate improvement or could not tolerate anti-muscarinic therapy. However, there is no evidence that PTNS cures UUI in women. In addition, PTNS is no more effective than tolterodine for improvement of UUI in women. In men there is insufficient evidence to reach a conclusion about efficacy.

T-PTNS

A small RCT compared transcutaneous PTNS plus standard treatment (PFMT and BT) with PFMT and BT alone in older women [189]. Women in the T-TPNS group were more likely to achieve improvement at the end of therapy.

4.1.3.4.3 Summary of evidence for posterior tibial nerve stimulation

Summary of evidence	LE
Percutaneous posterior tibial nerve stimulation appears effective for improvement of UUI in women who have had no benefit from antimuscarinic medication.	2b
A maintenance programme of P-PTNS has been shown to be effective up to three years.	1b
Percutaneous Posterior tibial nerve stimulation has comparable effectiveness to tolterodine for improvement of UUI in women.	1b
No serious adverse events have been reported for P-PTNS in UUI.	3
There is limited evidence for effectiveness of T-PTNS.	2a
There is no evidence that P-PTNS cures UI.	2b

P-PTNS = Percutaneous posterior tibial nerve stimulation; T-PTNS = transcutaneous posterior tibial nerve stimulation; UI=urinary incontinence; UUI=urge urinary incontinence.

4.1.3.5 Recommendations for behavioural and physical therapies

Recommendations	Strength rating
Offer prompted voiding for adults with UI who are cognitively impaired.	Strong
Offer bladder training as a first-line therapy to adults with UUI or MUI.	Strong
Offer supervised intensive PFMT, lasting at least 3 months, as a first-line therapy to all women with SUI or MUI (including the elderly and post-natal).	Strong

Offer instruction on PFMT to men undergoing radical prostatectomy to speed recovery from UI.	Strong
Ensure that PFMT programmes are as intensive as possible.	Strong
Do not offer ES with surface electrodes (skin, vaginal, anal) alone for the treatment of stress UI.	Strong
Do not offer magnetic stimulation for the treatment of UI or overactive bladder in adult women.	Strong
Consider PTNS as an option for improvement of UUI in women who have not benefited from antimuscarinic medication.	Strong

ES = electrical stimulation; MUI = mixed urinary incontinence; PFMT = pelvic floor muscle training; PTNS = percutaneous tibial nerve stimulation; SUI = stress urinary incontinence; UI = urinary incontinence; UUI = urge urinary incontinence.

*4.1.4 **Conservative therapy in mixed urinary incontinence***

About one-third of women with UI have MUI with symptoms of both SUI and UUI, and this becomes more common with increasing age. In terms of evidence base, many studies include patients with MUI, but it is rare for these studies to provide a separate analysis of patients with MUI.

4.1.4.1 Question

In adults with MUI, is the outcome of conservative therapy different to that obtained with the same treatment in patients with either pure SUI or pure UUI?

4.1.4.2 Evidence

No specific SRs were found that addressed the above question. However, a Cochrane report on PFMT [166] concluded that training was less likely to result in a cure in patients with MUI than in patients with pure SUI, though it is not clear from the report how this conclusion was reached.

A small RCT (n = 71) compared delivery of PFMT, with or without an instructive audiotape. It showed equal efficacy for different types of UI [190].

Following a RCT of PFMT, a review of 88 women available for follow-up at five years found that outcomes were less satisfactory in women with MUI than in women with pure SUI [191].

4.1.4.3 Summary of evidence and recommendations for conservative therapy in mixed urinary incontinence

Summary of evidence	**LE**
Pelvic floor muscle training appears less effective for MUI than for SUI alone.	2
Electrical stimulation is equally effective for MUI and SUI.	1b

Recommendation	**Strength rating**
Treat the most bothersome symptom first in patients with MUI.	Weak

MUI = mixed urinary incontinence; SUI = stress urinary incontinence.

4.2 Pharmacological management

*4.2.1 **Antimuscarinic drugs***

Antimuscarinic (anticholinergic) drugs are currently the mainstay of treatment for UUI. They differ in their pharmacological profiles, e.g. muscarinic receptor affinity and other modes of action, in their pharmacokinetic properties, e.g. lipid solubility and half-life, and in their formulation.

The evaluation of cure or improvement of UI is made harder by the lack of a standard definition of improvement and the failure to use cure as a primary outcome. In general, SRs note that the overall treatment effect of drugs is usually small but larger than placebo.

Dry mouth is the commonest side effect, though constipation, blurred vision, fatigue and cognitive dysfunction may occur [162].

The immediate release (IR) formulation of oxybutynin is the archetype drug in the treatment of UUI. Oxybutynin IR provides maximum dosage flexibility, including an off-label ‘on-demand’ use. Immediate-release drugs have a greater risk of side effects than extended release (ER) formulations because of differing pharmacokinetics. A transdermal delivery system (TDS) and gel developed for oxybutynin gives a further alternative formulation.

4.2.1.1 Question

In adults with UUI, are antimuscarinic drugs better than placebo for improvement or cure of UUI and for the risk of adverse effects?

4.2.1.2 Evidence

Seven SRs of individual antimuscarinic drugs vs. placebo were reviewed for this section [162, 192-197] as well as studies published since these reviews up until April 2016. Most studies included patients with a mean age of 55-60 years. Both female and male subjects were included in different studies but results cannot be generalised across sexes. Only short-term rates for improvement or cure of UUI are reported. The evidence reviewed was consistent, indicating that ER and IR formulations of antimuscarinics offer clinically significant short-term cure and improvement rates for UUI compared to placebo. On balance, IR formulations tend to be associated with more side effects compared to ER formulations [196].

Cure of UI was deemed to be the most important outcome measure. Risk of adverse events was best represented by withdrawal from a trial because of adverse events, although this does not reflect practice. Table 2 shows a summary of the findings from a SRs [162]. In summary, every drug where cure of UI was available shows superiority compared to placebo in achieving UI, but the absolute size of effect is small. There is limited evidence that patients who do not respond to a first-line antimuscarinic treatment may respond to a higher dose or a different antimuscarinic agent [198, 199].

Table 2: Summary of cure rates and discontinuation rates of antimuscarinic drugs from RCTs which reported these outcomes [162]

Drug	**No. of studies**	**Patients**	**Relative risk (95% CI) (of curing UI)**	**Number needed to treat (95% CI) (to achieve one cure of UI)**
Cure of incontinence				
Fesoterodine	2	2,465	1.3 (1.1-1.5)	8 (5-17)
Oxybutynin (includes IR)	4	992	1.7 (1.3-2.1)	9 (6-16)
Propiverine (includes IR)	2	691	1.4 (1.2-1.7)	6 (4-12)
Solifenacin	5	6,304	1.5 (1.4-1.6)	9 (6-17)
Tolterodine (includes IR)	4	3,404	1.2 (1.1-1.4)	12 (8-25)
Trospium (includes IR)	4	2,677	1.7 (1.5-2.0)	9 (7-12)
Discontinuation due to adverse events				
			Relative Risk (95% CI) (of discontinuation)	**NNT (95% CI) (of one discontinuation)**
Darifenacin	7	3,138	1.2 (0.8-1.8)	
Fesoterodine	4	4,433	2.0 (1.3-3.1)	33 (18-102)
Oxybutynin (includes IR)	5	1,483	1.7 (1.1-2.5)	16 (8-86)
Propiverine (includes IR)	2	1,401	2.6 (1.4-5)	29 (16-77)
Solifenacin	7	9,080	1.3 (1.1-1.7)	78 (39-823)
Tolterodine (includes IR)	10	4,466	1.0 (0.6-1.7)	
Trospium (includes IR)	6	3,936	1.5 (1.1-1.9)	56 (30-228)

CI = confidence interval; NNT = number to treat; UI = urinary incontinence.

4.2.1.2.1 Darifenacin

The cure rates for darifenacin were not included in the AHRQ review. Continence rates were 29-33% for darifenacin compared to 17-18% for placebo [162].

4.2.1.2.2 Transcutaneous oxybutynin

Transdermal oxybutynin has shown a significant improvement in the number of incontinence episodes and micturitions per day vs. placebo and other oral formulations but continence was not reported as an outcome [162].

Oxybutynin topical gel was superior to placebo for improvement of UUI with a higher proportion of participants being cured [162, 200].

4.2.2 ***Comparison of antimuscarinic agents***

Head-to-head comparison trials of the efficacy and side effects of different antimuscarinic agents are of interest for decision making in practice.

4.2.2.1 Question

In adults with UUI, does one type of antimuscarinic drug result in a greater likelihood of cure or improvement in UUI, and/or a greater improvement in QoL, and/or a lesser likelihood of adverse effects compared to an alternative antimuscarinic drug?

4.2.2.2 Evidence

There are over 40 RCTs and eight SRs [162, 181, 192, 194, 197, 201-203]. Nearly all the primary studies were industry sponsored. Upward dose titration is often included in the protocol for the experimental arm, but not for the comparator arm.

In general, these studies have been designed for regulatory approval. They have short treatment durations (twelve weeks) and a primary outcome of a change in OAB symptoms rather than a cure of, or an improvement in, UUI, which were generally analysed as secondary outcomes. The clinical utility of these trials in real life practice is questionable. Most trials were of low or moderate quality [194]. The 2012 AHRQ review included a specific section addressing comparisons of antimuscarinic drugs (Table 2).

Fesoterodine

Results of an RCT of fesoterodine 4 vs. 8 mg suggested a larger therapeutic effect on UUI with the higher dose but with more adverse events [198].

No antimuscarinic agent improved QoL more than another agent [194]. Dry mouth is the most prevalent adverse effect. Good evidence indicates that, in general, higher doses of any drug are likely to be associated with higher rates of adverse events. Also, ER formulations of short-acting drugs and longer-acting drugs are generally associated with lower rates of dry mouth than IR preparations [194, 201]. Oxybutynin IR showed higher rates of dry mouth than tolterodine IR and trospium IR, but lower rates of dry mouth than darifenacin, 15 mg daily [194, 201]. Overall, oxybutynin ER has higher rates of dry mouth than tolterodine ER, although the incidence of moderate or severe dry mouth were similar. Transdermal oxybutynin had a lower rate of dry mouth than oxybutynin IR and tolterodine ER, but had an overall higher rate of withdrawal due to an adverse skin reaction [194]. Solifenacin, 10 mg daily, had higher rates of dry mouth than tolterodine ER [194]. Fesoterodine, 8 mg daily, had a higher rate of dry mouth than tolterodine, 4 mg daily [204-206]. In general, similar discontinuation rates were observed, irrespective of differences in the occurrence of dry mouth (doses have been given were the evidence relates to a specific dose level typically from trials with a dose escalation element).

4.2.2.3 Summary of evidence for antimuscarinic agents

Summary of evidence	**LE**
There is limited evidence that one antimuscarinic drug is superior to an alternative antimuscarinic drug for cure or improvement of UUI.	1b
Higher doses of antimuscarinic drugs are more effective to cure or improve UUI, but with a higher risk of side effects.	1b
Once daily (extended release) formulations are associated with lower rates of adverse events compared to immediate release ones, although similar discontinuation rates are reported in clinical trials.	1b
Dose escalation of antimuscarinic drugs may be appropriate in selected patients to improve treatment effect although higher rates of adverse events can be expected.	1b
Transdermal oxybutynin (patch) is associated with lower rates of dry mouth than oral antimuscarinic drugs, but has a high rate of withdrawal due to skin reaction.	1b

UUI=urge urinary incontinence.

4.2.3 ***Antimuscarinic drugs vs. conservative treatment***

The choice of drug vs. conservative treatment of UUI is an important question.

4.2.3.1 Question

In adults with UUI, does one type of antimuscarinic drug result in a greater likelihood of cure or improvement in UUI and/or greater improvement in QoL, and/or lesser likelihood of adverse effects compared to conservative treatment?

4.2.3.2 Evidence

More than 100 RCTs and high-quality reviews are available [163, 181, 194, 195, 207, 208]. Most of these studies were independent. A US HTA [181] found that trials were of a low- or moderate-quality. The main focus of the review was to compare the different drugs used to treat UUI. In one study, multicomponent behavioural modification produced significantly greater reductions in incontinence episodes compared to oxybutynin and higher patient satisfaction for behavioural vs. drug treatment. In men with storage LUTS no difference in efficacy was found between oxybutynin and behavioural therapy [209].

The combination of BT and solifenacin in women with OAB conferred no additional benefit in terms of continence [210]. A recent Cochrane review on the benefit of adding PFMT to other active treatments of UI in women showed insufficient evidence of any benefit in adding PFMT to drug treatment [211].

One RCT [212] reported a similar improvement in subjective parameters with either transcutaneous electrical nerve stimulation (T-PTNS) or oxybutynin. One study compared tolterodine ER to transvaginal/anal ES without differences in UI outcomes [213].

4.2.3.3 Summary of evidence and recommendations for antimuscarinic drugs

Summary of evidence	**LE**
There is no consistent evidence to show superiority of drug therapy over conservative therapy for treatment of UUI.	1b
Behavioural treatment has higher patient satisfaction than drug treatment.	1b
There is insufficient evidence as to the benefit of adding PFMT to drug treatment for UUI.	1b

Recommendations	**Strength rating**
Offer antimuscarinic drugs for adults with UUI who failed conservative treatment.	Strong
Consider extended release formulations of antimuscarinics drugs, whenever possible.	Strong
If an antimuscarinic treatment proves ineffective, consider dose escalation or offering an alternative antimuscarinic formulation, or mirabegron, or a combination.	Strong
Encourage early review (of efficacy and side effects) of patients on antimuscarinic medication for UUI.	Strong

PFMT = pelvic floor muscle training; UUI = urgency urinary incontinence.

*4.2.4 **Antimuscarinic agents: adherence and persistence***

Most studies on antimuscarinic medication are short term (twelve weeks). Adherence in clinical trials is considered to be much higher than in clinical practice [214].

4.2.4.1 Question

Do patients with UUI adhere to antimuscarinic drug treatment and persist with prescribed treatment in clinical practice?

4.2.4.2 Evidence

This topic has been reviewed for the development of these Guidelines [215]. Two open-label extensions of RCTs of fesoterodine 8 mg showed adherence rates at two years of 49-84% [216, 217]. The main drugs studied were oxybutynin and tolterodine IR and ER. Non-persistence rates were high for tolterodine at twelve months, and particularly high (68-95%) for oxybutynin.

Five articles reported 'median days to discontinuation' as between < 30 days and 50 days [218-222]. In a military health system where free medication was provided, the median time to discontinuation extended to 273 days [219].

Data on adherence/persistence from open-label extension populations are questionable as these patients are self-selected to be compliant. A Longitudinal Disease Analyser database study has indicated an increasing discontinuation rate from 74.8% at one year to 87% at three years [223].

Several of the RCT trials tried to identify the factors associated with low/lower, adherence or persistence of antimuscarinics. These were identified as:

- low level of efficacy (41.3%);
- adverse events (22.4%);
- cost (18.7%), higher adherence rates were observed when drugs were provided at no cost to the patient [219].

Other reasons for poor adherence included:

- IR vs. ER formulations;
- age (lower persistence among younger adults);
- unrealistic expectations of treatment;
- gender distribution (better adherence/persistence in female patients);
- ethnic group (African-Americans and other ethnic minorities are more likely to discontinue or switch treatment).

In addition, the data source influenced the adherence figures.

4.2.4.3 Summary of evidence for adherence to antimuscarinic treatment

Summary of evidence	**LE**
Adherence to antimuscarinic treatment is low and decreases over time because of lack of efficacy, adverse events and/or cost.	2
Most patients will stop antimuscarinic agents within the first three months.	2

*4.2.5 **Mirabegron***

Mirabegron is the first clinically available beta3 agonist, available from 2013. Beta3 adrenoceptors are the predominant beta receptors expressed in the smooth muscle cells of the detrusor and their stimulation is thought to induce detrusor relaxation.

Mirabegron has undergone evaluation in industry-sponsored phase 2 and phase 3 trials [224-227]. Three SRs assessing the clinical effectiveness of mirabegron [224, 225, 228] reported that mirabegron at doses of 25, 50 and 100 mg, results in significantly greater reduction in incontinence episodes, urgency episodes and micturition frequency/24 hours than placebo, with no difference in the rate of common adverse events [224]. The placebo dry rates in most of these trials are between 35-40%, and 43 and 50% for mirabegron. In all trials the statistically significant difference is consistent only for improvement but not for cure of UI. Similar improvement in frequency of incontinence episodes and micturitions/24 hours was found in people who had previously tried and those who had not previously tried antimuscarinic agents. One SR showed that mirabegron is similarly efficacious as most antimuscarinics in reducing UUI episodes [229].

The most common treatment adverse events in the mirabegron groups were hypertension (7.3%), nasopharyngitis (3.4%) and UTI (3%), with the overall rate similar to placebo [224, 227, 230].

In a twelve-month, active-controlled RCT of mirabegron 50/100 mg vs. tolterodine ER 4 mg, the improvement in efficacy seen at twelve weeks was sustained at twelve-month evaluation in all groups. The reported dry rates at twelve months were 43%, 45% and 45% for mirabegron 50 mg, 100 mg and tolterodine 4 mg respectively [230]. *Post-hoc* analyses of RCTs showed that clinical improvement observed in parameters of OAB severity translates to an improvement in HRQoL and efficacy is maintained in patients with more severe degree of UI [231, 232].

No risk of QTc prolongation on electrocardiogram [233] and raised intraocular pressure [234] were observed up to 100 mg dose; however, patients with uncontrolled hypertension or cardiac arrhythmia were excluded from these trials. There is no significant difference in rate of side effects at different doses of mirabegron [230]. Data from a large Canadian Private Drug Plan database suggest a higher adherence rate for mirabegron compared to antimuscarinics [235]. Patients on certain concurrent medications (i.e. metroprolol) should be counselled that, due to common metabolism pathways, their medication dosage may need to be adjusted. In the case of patients taking metoprolol, blood pressure should be monitored after starting mirabegron and, if necessary, metoprolol dosing changed.

Evaluation of urodynamic parameters in men with combined bladder outlet obstruction (BOO) and OAB concluded that mirabegron (50 or 100 mg) did not adversely affect voiding urodynamic parameters compared to placebo [236].

Equivalent adherence was observed for tolterodine and mirabegron at twelve months (5.5% and 3.6%), although the incidence of dry mouth was significantly higher in the tolterodine group [230]. In mirabegron treated patients, improvement in objective outcome measures correlates directly with clinically relevant PROMs (OAB-q and PPBC) [231, 237].

An RCT in patients who had inadequate response to solifenacin monotherapy 5 mg, demonstrated that combination treatment with mirabegron 50 mg had a higher chance of achieving clinically meaningful improvement in UI as compared to dose escalation of solifenacin [238].

4.2.5.1 Summary of evidence and recommendations for mirabegron

Summary of evidence	**LE**
Mirabegron is better than placebo and as efficacious as antimuscarinics for improvement of UUI symptoms.	1a
Adverse event rates with mirabegron are similar to placebo.	1a
Patients inadequately treated with solifenacin 5 mg may benefit more from the addition of mirabegron than dose escalation of solifenacin.	1b

Recommendation	**Strength rating**
Offer antimuscarinic drugs or mirabegron to adults with UUI who failed conservative treatment.	Strong

UUI = urgency urinary incontinence.

4.2.6 ***Antimuscarinic and beta3 agonist agents, the elderly and cognition***

Trials have been conducted in elderly people with UI. Considerations in this patient group include the multifactorial aetiology of UI in the elderly, comorbidities such as cognitive impairment, the effect of co-medications and the risk of adverse events.

The effects of antimuscarinic agents on cognition have been studied in more detail.

4.2.6.1 Question

What is the comparative efficacy, and risk of adverse effects, particularly the cognitive impact, of treatment with antimuscarinic medication in elderly men and women with UUI?

4.2.6.2 Evidence

Two SRs focusing on elderly patients are available [239, 240]. A community-based cohort study found a high incidence of cognitive dysfunction [241]. Other SRs have included sections on the efficacy and safety of antimuscarinics in elderly patients [162, 194]. A SR in 2012 found inconclusive evidence as to the impact of antimuscarinics on cognition [242].

Two recent longitudinal cohort studies in patients using drugs with antimuscarinic effect showed a deterioration in cognitive function, alteration in CNS metabolism and an association with brain atrophy [243, 244]. In general, the long-term impact of antimuscarinic agents specifically approved for OAB treatment on specific patient cohorts is poorly understood [245-248].

4.2.6.2.1 Oxybutynin

There is evidence that oxybutynin IR may cause/worsen cognitive dysfunction in adults [245, 247, 249-253]. Recent evidence has emerged from a prospective cohort study showing cumulative cognitive deterioration associated with prolonged use of antimuscarinic medication including oxybutynin [243].

More rapid functional deterioration might result from the combined use of cholinesterase inhibitors with antimuscarinic agents in elderly patients with cognitive dysfunction [254].

4.2.6.2.2 Solifenacin

One pooled analysis [255] has shown that solifenacin does not increase cognitive impairment in the elderly. No age-related differences in the pharmacokinetics of solifenacin in different age groups was found, although more frequent adverse events in subjects over 80 years of age were observed. No cognitive effect on healthy elderly volunteers was shown [253]. In a subanalysis of a large trial, solifenacin 5-10 mg improved symptoms and QoL in people ≥ 75 years who had not responded to tolterodine [256]. In patients with mild cognitive impairment, ≥ 65 years, solifenacin showed no difference in efficacy between age groups and a lower incidence of most side effects compared to oxybutynin IR [252, 257].

4.2.6.2.3 Tolterodine

No change in efficacy or side effects related to age have been reported, although a higher discontinuation rate was found for both tolterodine and placebo in elderly patients [245]. Two RCTs in the elderly found a similar efficacy and side effect profile to younger patients [258-261]. *Post-hoc* analysis has shown little effect on cognition. One non-randomised comparison showed lower rates of depression in elderly participants treated with tolterodine ER compared to oxybutynin IR [262].

4.2.6.2.4 Darifenacin

Two RCTs in the elderly population (one in patients with UUI and the other in volunteers) concluded that darifenacin was effective with no risk of cognitive change, measured as memory scanning tests, compared to placebo [263, 264]. Another study on darifenacin and oxybutynin ER in elderly subjects concluded that the two agents had a similar efficacy, but that cognitive function was more often affected in the oxybutynin ER arm [247].

4.2.6.2.5 Trospium chloride

Trospium does not appear to cross the blood brain barrier in significant amounts in healthy individuals due to its molecular characteristics (quaternary amine structure and hydrophilic properties). Two (EEG) studies in healthy volunteers showed no effect from trospium whilst tolterodine caused occasional changes and oxybutynin caused consistent changes [265, 266]. No evidence as to the comparative efficacy and side effect profiles of trospium in different age groups in available. However, there is some evidence that trospium does not impair cognitive function [248, 267] and that it is effective compared to placebo in the elderly [268].

4.2.6.2.6 Fesoterodine

Pooled analyses of the RCTs of fesoterodine confirmed the efficacy of the 8 mg but not the 4 mg dose in over 75-year olds [216]. Adherence was lower in the over-75 year-old group but the effect on mental status was not reported [206, 216, 269]. A more recent RCT showed efficacy of fesoterodine in the vulnerable elderly with no differences in cognitive function at twelve weeks [270].

4.2.6.2.7 Anti-incontinence drugs in the elderly

RCTs comparing duloxetine and placebo included women up to 85 years, but no age stratification of the results is available [195, 271, 272].

4.2.6.2.8 Mirabegron

Analysis of pooled data from three RCTs showed efficacy and safety of mirabegron in elderly patients [273].

4.2.6.2.9 Applicability of evidence to general elderly population

It is not clear how much the data from pooled analyses and subgroup analyses from large RCTs can be extrapolated to a general ageing population. Community-based studies of the prevalence of antimuscarinic side effects may be the most helpful [241]. When starting anticholinergics in elderly patients, mental function should be assessed objectively and monitored [274]. No consensus exists as to the best mental function test to detect changes in cognition [254, 275].

4.2.6.2.10 Anticholinergic load

A number of medications have anticholinergic effects and their cumulative effects on cognition should be considered [276].

4.2.6.2.11 Question

In older people suffering from UI, what is the effect of anticholinergic burden (defined by anticholinergic cognitive burden scale) on cognitive function?

4.2.6.2.12 Evidence

No studies were identified specifically in older people with UI, but evidence was available from observational cohort studies relating to the risk in a general population of older people. Lists of drugs with anticholinergic properties are available from two sources [276, 277].

Two SRs of largely retrospective cohort studies showed a consistent association between long-term anticholinergic use and cognitive dysfunction [278, 279].

Longitudinal studies in older people over two to four years have found increased rate of decline in cognitive function for patients on anticholinergics or drugs with anticholinergic effects [243, 244, 280, 281].

4.2.6.3 Summary of evidence and additional recommendations for use of antimuscarinic drugs in the elderly

Summary of evidence	LE
Antimuscarinic drugs are effective in elderly patients.	1b
Mirabegron has been shown to be efficacious and safe in elderly patients.	1b
In older people, the cognitive impact of drugs which have anticholinergic effects is cumulative and increases with length of exposure.	2
Oxybutynin may worsen cognitive function in elderly patients.	2
Solifenacin, darifenacin, fesoterodine and trospium have been shown not to cause cognitive dysfunction in elderly people in short-term studies.	1b

Recommendations	Strength rating
Long-term antimuscarinic treatment should be used with caution in elderly patients especially those who are at risk of, or have, cognitive dysfunction.	Strong

4.2.6.4 Research priorities

- All drug trials should report cure rates for UI based on a bladder diary.
- What is the relative incidence of cognitive side effects of antimuscarinic drugs?

4.2.7 ***Drugs for stress urinary incontinence***

Duloxetine inhibits the presynaptic re-uptake of neurotransmitters, serotonin (5-HT) and norepinephrine (NE). In the sacral spinal cord, an increased concentration of 5-HT and NE in the synaptic cleft increases stimulation of 5-HT and NE receptors on the pudendal motor neurones, which in turn increases the resting tone and contraction strength of the urethral striated sphincter.

4.2.7.1 Questions

- In adults with SUI, does duloxetine cure or improve UI and/or improve QoL compared to no treatment?
- In adults with SUI, does duloxetine result in a greater cure or improvement of UI, or a greater improvement in QoL, or a lesser likelihood of adverse effects, compared to any other intervention?

4.2.7.2 Evidence

Duloxetine was evaluated as a treatment for female SUI or MUI in three SRs [195, 271, 272].

Improvement in UI compared to placebo was observed with no clear differences between SUI and MUI. One study reported cure for UI in about 10% of patients. An improvement in I-QoL was not found in the study using I-QoL as a primary endpoint. In a further study comparing duloxetine, 80 mg daily, with PFMT alone, PFMT + duloxetine, and placebo [282], duloxetine reduced leakage compared to PFMT or no treatment.

Global improvement and QoL were better for combined therapy than no treatment. There was no significant difference between PFMT and no treatment.

Two open-label studies with a follow-up of one year or more evaluated the long-term effect of duloxetine in controlling SUI; however, both had high discontinuation rates [283, 284].

All studies had a high patient withdrawal rate, which was caused by a lack of efficacy and high incidence of adverse events, including nausea and vomiting (40% or more of patients), dry mouth, constipation, dizziness, insomnia, somnolence and fatigue, amongst other causes [283, 284].

A SR showed significant efficacy for duloxetine compared to placebo in women with UI but with increased risk of adverse events [272].

4.2.7.3 Summary of evidence and recommendations on drugs for SUI

Summary of evidence	LE
Duloxetine, 40 mg twice daily improves SUI in women.	1a
Duloxetine causes significant gastrointestinal and central nervous system side effects leading to a high rate of treatment discontinuation, although these symptoms are limited to the first weeks of treatment.	1a

Recommendations	Strength rating
Offer Duloxetine in selected patients with symptoms of SUI when surgery is not indicated.	Strong
Duloxetine should be initiated and withdrawn using dose titration because of high risk of adverse event.	Strong

SUI = stress urinary incontinence.

*4.2.8 **Oestrogen***

Oestrogenic drugs including conjugated equine oestrogens, oestradiol, tibolone and raloxifene, are used as hormone replacement therapy (HRT) for women with natural or therapeutic menopause.

Oestrogen treatment for UI has been tested using oral, transdermal and vaginal routes of administration. Available evidence suggests that vaginal oestrogen treatment with oestradiol and oestriol is not associated with the increased risk of thromboembolism, endometrial hypertrophy, and breast cancer seen with systemic administration [285-287]. Vaginal (local) treatment is primarily used to treat symptoms of vaginal atrophy in postmenopausal women.

4.2.8.1 Questions

- In women with UI, does vaginal (local) oestrogen cure or improve UI compared to no treatment or other active treatment?
- In women with UI, does oral (systemic) oestrogen cure or improve UI compared to no treatment?

4.2.8.2 Evidence

Vaginal oestrogens

A Cochrane SR looked at the use of oestrogen therapy in postmenopausal women [285] given local oestrogen therapy. There is also a more recent narrative review of oestrogen therapy in urogenital diseases [288].The Cochrane review (search date cut off June 2012) found that vaginal oestrogen treatment improved symptoms of UI in the short term [285]. The review found small, low quality trials comparing vaginal oestrogen treatment with phenylpropanolamine, PFMT, ES and its use as an adjunct to surgery for SUI. Local oestrogen was less likely to improve UI than PFMT but no differences in UI outcomes were observed for the other comparisons. A single trial of local oestrogen therapy comparing a ring device to pessaries found no difference in UI outcomes although more women preferred the ring device. No adverse effects of vaginal administration of oestradiol for vulvovaginal atrophy over two years was seen in one trial [289].

Vaginal oestrogen therapy can be given as conjugated equine oestrogen, oestriol or oestradiol in vaginal pessaries, vaginal rings or creams. The ideal treatment duration and the long-term effects are uncertain. A standardised review of local oestrogen showed improvement of UI over placebo with vaginal rings favoured subjectively over pessaries; no significant difference between vaginal and oral oestrogen treatments was found [290].

One RCT in postmenopausal women showed benefit in adding intravaginal oestriol to vaginal ES and PFMT [291].

Systemic oestrogens

Studies of HRT with non-urogenital primary outcomes have looked for change in urinary continence in secondary analyses. Large trials using conjugated equine oestrogens showed a higher rate of development or worsening of UI compared to placebo [292-295]. In a single RCT, use of raloxifene was not associated with development or worsening of UI [296]. Three small RCTs using oral oestriol or oestradiol as HRT for vulvovaginal atrophy suggested that UI symptoms were improved although the evidence was unclear [53, 297, 298].

4.2.8.3 Summary of evidence and recommendations for oestrogen therapy

Summary of evidence	LE
Vaginal oestrogen therapy improves UI for post-menopausal women in the short term.	1a
Neoadjuvant or adjuvant use of local oestrogens are ineffective as an adjunct to surgery for UI.	2
Systemic hormone replacement therapy using conjugate equine oestrogens in previously continent women increases the risk of developing UI and worsens pre-existing UI.	1a

Recommendations	Strength rating
Offer long-term vaginal oestrogen therapy to post-menopausal women with UI and symptoms of vulvo-vaginal atrophy.	Strong
In women with a history of breast cancer, the treating oncologist should be consulted.	Weak
For women taking oral conjugated equine oestrogen as hormone replacement therapy who develop or experience worsening UI, discuss alternative hormone replacement therapies.	Strong
Advise women who are taking systemic oestradiol who suffer from UI that stopping the oestradiol is unlikely to improve their incontinence.	Strong

UI = urinary incontinence.

*4.2.9 **Desmopressin***

Desmopressin is a synthetic analogue of vasopressin (also known as antidiuretic hormone). It can be taken orally, nasally or by injection. Desmopressin is most commonly used to treat diabetes insipidus and, when used at night, to treat nocturnal enuresis.

4.2.9.1 Questions

- In adults with UI, does desmopressin cure or improve UI and/or improve QoL compared to no treatment?
- In adults with UI, does desmopressin result in a lesser likelihood of adverse effects, compared to any other intervention?

4.2.9.2 Evidence

4.2.9.2.1 Improvement of incontinence

Few studies have examined the use of desmopressin exclusively for the treatment of UI. No evidence was found that demonstrated any effect of desmopressin on nocturnal incontinence, though evidence does exist for it reducing nocturnal polyuria, particularly in children [299]. One RCT compared desmopressin to placebo with daytime UI as an outcome measure, with improved continence shown during the first four hours after taking desmopressin in women [300].There is no evidence reporting desmopressin cure rates for UI and no evidence that compares desmopressin with other non-drug treatments for UI.

4.2.9.2.2 Monitoring for hyponatraemia

The use of desmopressin carries a risk of developing hyponatraemia (please refer to the EAU Guidelines on Male LUTS [30]).

4.2.9.3 Summary of evidence and recommendations for desmopressin

Summary of evidence	LE
The risk of UI is reduced within four hours of taking oral desmopressin, but not after four hours.	1b
Continuous use of desmopressin does not improve or cure UI.	1b
Regular use of desmopressin may lead to hyponatraemia.	3

Recommendations	Strength rating
Consider offering desmopressin to patients requiring occasional short-term relief from daytime UI and inform them that this drug is not licensed for this indication.	Strong
Monitor plasma sodium levels in patients on desmopressin.	Strong
Do not use desmopressin for long-term control of UI.	Strong

UI = urinary incontinence.

*4.2.10 **Drug treatment in mixed urinary incontinence***

4.2.10.1 Question

In adults with MUI, is the outcome of a drug treatment different to that for the same treatment in patients with either pure SUI or UUI?

4.2.10.2 Evidence

Many RCTs include patients with MUI with predominant symptoms of either SUI or UUI but few report outcomes separately for those with MUI compared to pure SUI or UUI groups.

Tolterodine

In an RCT of 854 women with MUI, tolterodine ER was effective for improvement of UUI, but not SUI suggesting that the efficacy of tolterodine for UUI was not altered by the presence of SUI [301]. In another

study (n = 1380) tolterodine was equally effective in reducing urgency and UUI symptoms, regardless of whether there was associated SUI [302]. Similar results were found for solifenacin [303, 304].

Duloxetine
In one RCT of duloxetine vs. placebo in 588 women, subjects were stratified into either stress-predominant, urgency-predominant or balanced MUI groups. Duloxetine was effective for improvement of incontinence and QoL in all subgroups [305].

Duloxetine was found to have equal efficacy for SUI and MUI in an RCT (n = 553) following secondary analysis of respective subpopulations [306].

4.2.10.3 Summary of evidence and recommendations for drug treatment in mixed urinary incontinence

Summary of evidence	**LE**
Limited evidence suggests that antimuscarinic drugs are effective for improvement of the UUI component in patients with MUI.	2
Duloxetine is effective for improvement of both SUI and UUI in patients with MUI.	1b

Recommendations	**Strength rating**
Treat the most bothersome symptom first in patients with MUI.	Weak
Offer antimuscarinic drugs or beta3 agonists to patients with urgency-predominant MUI.	Strong
Consider offering duloxetine for patients with MUI unresponsive to other conservative treatments and who are not seeking cure.	Strong

MUI = mixed urinary incontinence; SUI=stress urinary incontinence; UUI=urge urinary incontinence.

4.3 Surgical management

In line with the recommendations from the UK National Institute for Healthcare and Clinical Excellence (NICE) [53] the Panel agreed that surgeons and centres performing surgery should:
- be trained in the field of incontinence and for each surgical procedure they perform/offer;
- not be trained by someone who is not surgically qualified;
- perform sufficient numbers of a procedure to maintain expertise of him/herself and the surgical team;
- be able to offer alternative surgical treatments;
- be able to deal with the complications of surgery;
- provide suitable arrangements for long-term follow-up.

This section considers surgical options for:
- Women with uncomplicated SUI: This means no history of previous surgery, no neurogenic LUT dysfunction, no bothersome genitourinary prolapse, and women not considering further pregnancy.
- Women with complicated SUI: Neurogenic LUT dysfunction is reviewed in the EAU Guidelines on Neuro-Urology [2].
- Associated genitourinary prolapse has been included in these Guidelines in terms of treating incontinence, but no attempt has been made to comment on treatment of prolapse itself.
- Men with SUI: mainly men with post-prostatectomy incontinence without neurological disease affecting the LUT.
- Patients with refractory DO and low compliance bladders.

Although the outcome of surgical procedures should be considered in terms of cure, it is also important to consider any associated complications, adverse events and costs. The outcome parameters used to evaluate surgery for SUI have included:
- continence rate and number of incontinence episodes;
- patient-reported outcome measures;
- general and procedure-specific complications;
- generic, specific (UI) and correlated (sexual and bowel) QoL.

In this context it has to be taken into account that a number of products may no longer be available and therefore the recommendations may not be transferable to current devices. The Panel makes a strong recommendation that new devices are only used as part of a structured research programme and their outcomes monitored in a registry.

4.3.1 ***Women with uncomplicated stress urinary incontinence***

4.3.1.1 Mid-urethral slings

Early clinical studies identified that non-autologous slings should be made from monofilament, non-absorbable material, typically polypropylene, and constructed as a 1-2 cm wide mesh with a relatively large pore size (macroporous). Mid-urethral slings are now the most frequently used surgical intervention in Europe for women with SUI.

Safety of mid-urethral slings

A population-based study performed in Scotland on over 16,000 women operated on for SUI showed a similar rate of complications between mesh and non-mesh surgery confirming the safety of mesh procedure for UI [307]. However, a recent study of over 92,000 patients followed in the National Health Service (UK) showed a significant (9.8%) rate of complications using a more broad definition and following patients for a longer period of time. These findings suggest that, as with any SUI surgery, mid-urethral sling (MUS) surgery can be associated with complications and proper informed consent is mandatory.

4.3.1.1.1 Questions

In women with SUI, what is the effectiveness in curing SUI and adverse effects for:

- mid-urethral synthetic sling insertion compared to Burch colposuspension?
- one method of insertion of a MUS compared to another method?
- one direction of insertion of a MUS compared to another direction of insertion?
- colposuspension compared to autologous fascial sling.

4.3.1.1.2 Evidence

For the purpose of these Guidelines, a new meta-analysis was performed.

A Cochrane review of open retropubic colposuspension in the treatment on UI was published in 2016 [308]. Overall, colposuspension is associated with a continence rate of 85-90% at 1 to 5 years post-operatively and about 70% of patients can expect to be dry after five years. Comparison of colposuspension vs. MUS showed non difference in subjective or objective evaluation of incontinence rates at any time point (one to five years and five years and more time points). A subanalysis of autologous fascialslings showed better effectiveness compared to colposuspension at one to five years follow-up. In a RCT of Burch colposuspension vs. autologous fascial slings, continence rates decreased substantially over time in both arms. At five years, continence rate of colposuspension was 24.1% compared to 30.8% for fascial slings, satisfaction remained higher in the sling group (83% vs. 73%) and was related to the continence status [309]. Adverse events rates were similar for the two treatment groups with Burch 10% and sling 9% although post-operative obstruction was found exclusively in the sling group.

In general, open retropubic colposuspension does not seem to be associated with higher morbidity and complications compared to MUS. Pelvic organ prolapse is more common after colposuspension and voiding dysfunction occurs more often after MUS [308].

Transobturator route vs. retropubic route

A Cochrane meta-analysis of mid-urethral sling procedures for SUI in women was performed in 2017 spanning January 1947 to June 2014 [310]. Moderate quality evidence from 55 studies showed variable, but comparable, subjective cure rates between retropubic and transobturator slings (62-98% in the transobturator arms and 71-97% in the retropubic arms) in the short term (up to one year). No difference in the objective cure rate in the short term was found. A lower number of studies provide medium (one to five years) and long-term (over five years) follow-up with no difference in the subjective cure rates in the mid- and long-term. In the long term, a subjective cure rate of 43-92% in the transobturator group and of 51-88% in the retropubic group was found.

Although the adverse event rates are low, the retropubic approach was associated with a higher rate of bladder perforation (4.5% vs. 0.6%) and voiding dysfunction; vascular and visceral injury, mean operative time, operative blood loss and hospital stay were lower in the transobturator groups.

Transobturator surgery was associated with a lower risk of voiding dysfunction but groin pain was more frequent (6.4% vs. 0.6%). The opposite occurred for suprapubic pain (0.8% in the transobturator and 2.9% in the retropubic groups, respectively). The overall vaginal erosion risk was low and comparable in both groups (2.1% in retropubic and 2.4% in transobturator surgery). Re-do surgery for UI was more common in the transobturator group (RR = 8.79, 95% CI: 3.36-23) however the data is limited and of low quality

In retropubic surgery, the bottom-to-top route was 10% more efficacious than top-to-bottom in terms of subjective cure and it was associated with less voiding dysfunction, bladder perforations and vaginal erosion.

Analysis of the TOMUS trial (a randomised equivalence trial of retropubic vs. transobturator MUS for the treatment of SUI in women) confirms equivalence of objective cure rates at 12 but not at 24 months (77.3% and 72.3% objective cure rate for retropubic and transobturator surgery). Subjective cure rates are inconclusive for equivalence. Patient satisfaction (86.3% vs. 88.1%), frequency of *de novo* UUI (0% vs. 0.3%) and mesh exposure (4.4% vs. 2.7%) did not differ significantly between the retropubic and transobturator groups. Subjective and objective treatment success continues to decrease over time and equivalence of the retropubic and the transobturator routes cannot be confirmed at 24 and 60 months with retropubic demonstrating a slight benefit, however satisfaction remained high in both arms [311]. The cumulate rate of serious adverse events was nearly twice as high in the retropubic group compared with the transobturator group at 24 months, but they occurred much less often in the second year of follow-up [312].

An economic evalution of retropubic vs. transobsturator tapes suggests that the latter may be cost-effective and cost-saving compared to the standard tension-free vaginal tape (TVT) approach over a five years period [313].

Ten years data are available from a RCT of TVT, xenograft and autologous fascial slings. Dry rates were 31.7%, 50.8% and 15.7% at ten years, for TVT, autologous and Pelvicol™ fascial slings, respectively, down from 55%, 48% and 22% measured at one year follow-up. Re-operation rates at ten years were 3.2% in the TVT group, none in the autologous fascial sling arm and 13.1% in the Pelvicol group [314]. Satisfaction rates were 69.3%, 70.1%, 52.6% for TVT, autologous and Pelvicol fascial slings, respectively.

Long-term results of a RCT comparing TVT vs. inside-out trans-obturator tape (TOT) showed a 79.3% and a 69.4% objective cure rate at 95 months, however patient-reported cure rates were 74.1% and 61.3%, respectively. The long-term complication rates for TVT and TVT-O were 43.1% and 27.4% respectively ($p = 0.07$). [315].

Surgery in obese women

There is no agreement as to the outcome of incontinence surgery in obese women. Secondary analysis of a RCT on retropubic and transobturator tapes in the treatment of women with SUI suggests that obese women experience inferior outcome compared to non-obese women. Stratification of patients according to BMI (< 30 and ≥ 30) shows significant difference in objective dry rates (negative pad test) at one (85.6% vs. 67.8%) and five years (87.4% vs. 65.9%) and subjective cure (absence of SUI symptoms) at one (85.8% vs. 70.7%) and five years (76.7% vs. 53.6%, respectively). Between one and five years, 6.7% and 16.3% of patients initially dry (negative pad test) after surgery developed a positive pad test, respectively [316, 317].

Conversely, short-term outcome of single-incision MiniArc sling showed comparable objective cure rates (negative cough stress test) at two years (86% and 81% in non-obese and obsese women, respectively); similar improvement of the Urinary Distress Inventory 6 and Incontinence Impact questionnaire 7 was observed in non-obese and obese women [318].

Long-term outcome of MUS (≥ 5 years)

Long-term follow-up of MUS is rarely available from RCTs and more often from cohort studies. Evaluation of the long-term (nine years) outcome of the E-TOT study using postal questionnaires showed a 71.6% patient-reported success rate (very/much improved) on the Patient's Global Impression of Improvement (PGI-I) scale. The nine-years success rates are lower than observed in the first year (80%) but comparable with the three-year follow-up (73.1%). Overall, 8% of patients had re-do surgery, tape extrusion/erosion rate was 4.5%, and groin pain/discomfort was reported in 4.32%, with only 1.4% requiring treatment [319].

Long-term efficacy of transobturator mid-urethral slings was confirmed by the ten-year follow-up of a large patient cohort with 92% cure rate (160 of 168 implanted patients were available for evaluation). *De novo* OAB developed in 14% of patients at ten years. History of failure of previous anti-incontinence procedures was the only predictor of recurrence of SUI (hazard ratio: 5.34; 95% CI: 2.61–11.9; $p = 0.009$) [320].

Long-term follow-up of patients treated with TVT showed a sustained response with 95.3%, 97.6%, 97.0% and 87.2% of patients being cured or improved at 5, 7, 11 and 17 years, respectively [321].

Another long-term cohort study of retropubic tension-free vaginal tape showed a 89.9% objective cure rate, a 76.1% subjective cure rate at ten years. Overall, 82.6% of patients reported to be highly satisfied with the surgery [322].

Insertion using a skin-to-vagina direction vs. a vagina-to-skin direction

A Cochrane review of MUS operations for female SUI showed no difference in the short and medium-term

subjective cure rates in medial-to-lateral vs. lateral-to-medial approaches based on moderate quality evidence [310]. Voiding dysfunction seems to be more frequent in the medial-to-lateral group but this approach is associated with a lower frequency of vaginal perforations (RR 0.25, 95% CI: 0.12-0.53; 3 trials). Because of the low quality of the evidence it is unclear whether the lower frequency of vaginal perforations of the medial-to-lateral approach is responsible for the observed lower rate of vaginal tape erosions.

A meta-analysis of RCTs demonstrated no significant difference in efficacy between lateral-to-medial vs. medial-to-lateral approaches, but vaginal perforations were less frequent in the medial-to-lateral group (2.6% vs. 11.8%, OR: 0.21, p = 0.0002) [323].

The five-year data of a prospective, non-randomised study of the two techniques showed a very high objective success rate (82.6 vs. 82.5%, respectively) with no difference between the two approaches [324].

In a secondary analysis of the E-TOT study (a study of transobturator tension-free vaginal tapes in the treatment of women with urodynamic MUI), no difference in the patient-reported success rates was found between the inside-out and the outside-in groups (63.2% and 65.5%, respectively; OR 1.11, 95% CI: 0.33-3.70, P > 0.999) at 9 years follow-up [325].

4.3.1.2 Adjustability

4.3.1.2.1 Questions

- In women with SUI, does an adjustable sling cure SUI and improve QoL or does it cause adverse outcome(s)?
- How does an adjustable sling compare with other surgical treatments for SUI?

4.3.1.2.2 Evidence

There are no RCTs investigating outcome of adjustable sling insertion for women with SUI. There are limited data from cohort studies on adjustable tension slings with variable selection criteria and outcome definitions. Few studies include sufficient numbers of patients or have a long enough follow-up to provide useful evidence. The available devices have differing designs, making it difficult to draw general conclusions about adjustable slings as a class of procedure.

4.3.1.3 Single-incision slings

4.3.1.3.1 Questions

- In women with SUI, do single-incision slings cure UI or improve QoL, or cause adverse outcomes?
- How does a single-incision sling compare to other surgical treatments for SUI?

4.3.1.3.2 Evidence

Although there have been many studies published on single-incision devices, it should be noted that there are significant differences in technical design between devices and it may be misleading to make general statements about them as a class of operations. It should also be noted that some devices have been withdrawn from the market (e.g. TVT Secur®, Minitape, MiniArc©), and yet evidence relating to these may be included in current meta-analyses. There was evidence to suggest single-incision slings are quicker to perform and cause less post-operative thigh pain, but there was no difference in the rate of chronic pain. There was insufficient evidence for direct comparisons between single-incision slings, and reach any conclusions about differences.

The most recent meta-analyses [326, 327] and a re-analysis of the Cochrane review data by the Panel (excluding TVT Secur® data) have demonstrated that there was no difference in efficacy between available single-incision devices and conventional mid-urethral slings at one year. However, not all single-incision devices have been subjected to RCT evaluation and it may be unsafe to assume that they are collectively technically similar devices.

Generalisability of evidence to adult women with SUI

Analysis of the population studied in trials included in this meta-analysis suggests that the evidence is generalisable to women who have predominantly SUI, and no other clinically severe LUT dysfunction. The evidence is not adequate to guide choice of surgical treatment for those women with MUI, severe POP, or a history of previous surgery for SUI. The results of the EAU Panel meta-analysis [328] were consistent with those of the Cochrane SR [329], except that in the EAU Panel meta-analysis the objective cure rates appeared slightly higher for retropubic (88%) compared to transobturator insertion (84%). The EAU Panel finding is consistent with an additional SR and meta-analysis [330] and the difference may result from the Panel's decision to only consider trial data with at least twelve months of follow-up.

Sexual function after mid-urethral tape surgery
A SR of the effect of female sexual function following mid-urethral slings suggested contradictory results, overall more papers show an improvement, or no change, in sexual function because of a reduction in coital incontinence, anxiety and avoidance of sex. Dyspareunia was the most common cause of worsening of sexual life [331].

A meta-analysis of outcome measures in trials of sling procedures suggests that single-incision slings are associated with a significantly higher improvement in sexual life compared to standard mid-urethral procedures [332].

SUI surgery in the elderly
An RCT of 537 women comparing retropubic to transobturator tape, showed that increasing age was an independent risk factor for failure of surgery over the age of 50 [333]. An RCT assessing risk factors for the failure of TVT vs. transobturator tension-free vaginal tape (TVT-O) in 162 women found that age is a specific risk factor (adjusted OR 1.7 per decade) for recurrence at one year [334]. In a sub-analysis of a trial cohort of 655 women at 2 years' follow-up, it was shown that elderly women were more likely to have a positive stress test at follow-up (OR 3.7, 95% CI: 1.7-7.97), are less likely to report objective or subjective improvement in stress and urgency UI, and are more likely to undergo re-treatment for SUI (OR 3.9, 95% CI: 1.3-11.48). There was no difference in time to post-operative normal voiding [335].

Another RCT comparing immediate TVT vs. no surgery (delayed TVT) in older women, confirmed efficacy of surgery in terms of QoL and satisfaction, but with complications in the surgical arm [336].

A cohort study evaluating 181 women undergoing TVT-O surgery, found that women over 70 years had similar outcomes when compared to women under 70 years old in terms of cure rates (92.5% vs. 88.3% p = 0.40), voiding dysfunction, vaginal erosion and groin pain at a median follow-up of 24 months [337].

A SR of the efficacy of treatments of UI in older patients suggests that MUS are successful in older patients (≥ 65 years) with 5.2-17.6% reporting persistent SUI after surgery. No difference in the frequency of *de novo* UUI, persistent UUI and persistant SUI was found in older patients [338].

4.3.1.3.3 Summary of evidence for mid-urethral slings

Summary of evidence	**LE**
The retropubic MUS provides equivalent patient-reported subjective and objective cure of SUI, compared with colposuspension.	1a
Mid-urethral synthetic slings inserted by either the transobturator or retropubic route provide equivalent patient-reported outcome at five years.	1a
Mid-urethral synthetic slings inserted by the retropublic routes has higher objective patient-reported cure rates at 8 years.	1b
Long-term analyses of MUS cohorts showed a sustained response beyond ten years.	2b
The retropubic route of insertion is associated with a higher intra-operative risk of bladder perforation and a higher rate of voiding dysfunction than the transobturator route.	1a
The transobturator route of insertion is associated with a higher risk of groin pain than the retropubic route.	1a
Long-term analysis showed no difference in terms of efficacy for the skin-to-vagina compared to vagina-to-skin directions up to nine years.	2a
The top-to-bottom direction in the retropubic approach is associated with a higher risk of post-operative voiding dysfunction.	1b
Adjustable mid-urethral synthetic sling devices may be effective for cure or improvement of SUI in women.	3
There is no evidence that adjustable slings are superior to standard MUS.	4
The comparative efficacy of single-incision slings against conventional MUS is uncertain.	1b
Operation times for insertion of single-incision MUS are shorter than for standard retropubic slings.	1b
Blood loss and immediate post-operative pain are lower for insertion of single-incision slings compared with conventional mid-urethral slings.	1b
There is no evidence that other adverse outcomes from surgery are more or less likely with single-incision slings than with conventional MUS.	1b
Incontinence surgery has similar outcomes in older patients (≥ 65 years).	2a

The risk of failure from surgical repair of SUI, or suffering adverse events, appears to increase with age.	2
There is no evidence that any surgical procedure has greater efficacy or safety in older women than another procedure.	4
Incontinence surgery may be safely performed in obese women, however, outcomes may be inferior.	2b
In women undergoing surgery for SUI, coital incontinence is likely to improve.	3
Overall, sexual function is unlikely to deteriorate following SUI surgery.	2a
Improvement in sexual life is higher with single incision slings than with standard MUS.	1a

MUS = mid-urethral sling; SUI = stress urinary incontinence; TVT = tension-free vaginal tape.

NB: Most evidence on single-incision slings is from studies using the tension-free vaginal tape secure (TVT-S) device and although this device is no longer available, many women still have the device in place.

4.3.1.4 Open and laparoscopic surgery for stress urinary incontinence

Open colposuspension was previously considered the most appropriate surgical intervention for SUI, and was used as the comparator in RCTs of newer, less invasive, surgical techniques. These include laparoscopic techniques, which have enabled colposuspension to be performed with a minimally invasive approach.

4.3.1.4.1 Question

In women with SUI, what is the effectiveness of open and laparoscopic surgery, compared to other surgical procedures, measured in terms of cure or improvement of incontinence or QoL, or the risk of adverse events?

4.3.1.4.2 Evidence

Four SRs were found, which covered the subject of open surgery for SUI, including 46 RCTs [2, 339-341]. Risk of re-operation for Burch colposuspension is estimated to 6% within 5 years [342] and 10.8% (95% CI: 9.3–12.3) within 9 years [343] .

Open colposuspension

The Cochrane review [308] included 55 trials in which 5,417 women had open colposuspension. In most of these trials, open colposuspension was used as the comparator to an experimental procedure. Consequently, for this review we have only considered the absolute effect of colposuspension, but have not reviewed all of these comparisons. No additional trials have been reported since this review.

Within the first year, complete continence rates of approximately 85-90% were achieved for open colposuspension, while failure rates for UI were 17% up to five years and 21% over five years. The re-operation rate for UI was 2%. Colposuspension was associated with a higher rate of development, at five years, of enterocoele/vault/cervical prolapse (42%) and rectocele (49%) compared to TVT (23% and 32%, respectively) but with a lower risk of voiding dysfunction compared to sling surgery. The rate of cystocoele was similar in colposuspension (37%) and with TVT (41%). The Cochrane review concluded that open colposuspension is an effective treatment for SUI and 70% of women can expect to be dry at five years after surgery.

Autologous fascial sling

The Cochrane review [340, 344] described 26 RCTs, including 2,284 women undergoing autologous sling procedure in comparison to other operations [345].

There were seven trials of autologous fascial sling vs. colposuspension. Except for one very high-quality study [52] showing superiority of fascial sling, most of the studies were of variable quality, with a few very small studies and short follow-up. The meta-analysis showed that fascial sling and colposuspension had a similar cure rate at one year. Colposuspension had a lower risk of voiding difficulty and UTIs, but a higher risk of bladder perforation.

In twelve trials of autologous fascial sling vs. mid-urethral synthetic slings, the procedures showed similar efficacy. However, use of the synthetic sling resulted in shorter operating times and lower rates of complications, including voiding difficulty. Six trials compared autologous fascial slings with other materials of different origins, with results favouring traditional autologous fascial slings. *Post-hoc* analysis of an RCT comparing the autologous fascial sling to Burch colposuspension showed inferior outcomes for women who suffered pre-operative urgency [335].

Laparoscopic colposuspension

The Cochrane review reported on twelve trials comparing laparoscopic colposuspension to open colposuspension. Although these procedures had a similar subjective cure rate, there was limited evidence suggesting the objective outcomes were less good for laparoscopic colposuspension. However, laparoscopic colposuspension had a lower risk of complications and shorter duration of hospital stay and may be slightly more cost-effective when compared with open colposuspension after 24 months follow-up.

In eight RCTs comparing laparoscopic colposuspension to MUS, the subjective cure rates were similar, while the objective cure rate favoured the mid-urethral sling at eighteen months. Complication rates were similar for the two procedures and operating times were shorter for the MUS. Comparisons of colposuspension to mid-urethral sling are covered in section 4.3.1.1.

Single-port laparoscopic Burch can be an alternative treatment for scarless surgery, though data confirming efficacy is limited [346].

4.3.1.4.3 Summary of evidence for open and laparoscopic surgery for stress urinary incontinence

Summary of evidence	**LE**
Autologous fascial sling is more effective than colposuspension for improvement of SUI.	1b
Autologous fascial sling has a higher risk of operative complications than open colposuspension, particularly voiding dysfunction and post-operative UTI.	1b
Colposuspension is associated with a higher long-term risk of POP than MUS.	1a
Laparoscopic colposuspension has a shorter hospital stay and may be more cost-effective than open colposuspension.	1a

POP = pelvic organ prolapse; SUI = stress urinary incontinence ; UTI = urinary tract infection.

4.3.1.5 Bulking agents

The concept of this procedure originates from the idea that intra or periurethral injection of an agent able to solidify under the submucosa or around the urethra, respectively, will form artificial cushions which increase the resistance to urine flow and facilitate continence.

4.3.1.5.1 Question

In women with SUI, does injection of a urethral bulking agent cure SUI or improve QoL, or cause adverse outcomes?

4.3.1.5.2 Evidence

A Cochrane review identified 14 randomised or quasi-randomised controlled trials of treatment for urinary incontinence in which at least one management arm involved periurethral or transurethral injection therapy [347]. Following this review, five additional reviews investigated the effect of injectables for the treatment of female SUI [348-352] but one review included results from RCTs only [352], independently of the injected material. Altogether, 1,814 patients were included from fourteen trials of seven different types of intraurethral injection: glutaraldehyde cross-linked collagen (Contigent©), a porcine dermal implant (Permacol©), solid silicone elastomer (Macroplastique©), autologous fat, pyrolytic carbon (Durasphere©), calcium hydroxylapatite (Coaptite©), hydrogel (Bulkamid©) and dextran polymer (Zuidex©). The heterogeneity of the populations, the variety of materials used and the lack of long-term follow-up limit guidance of practice. Most of the studies show a tendency for a short-term improvement in urinary incontinence, with the exception of a RCT which could not find difference between saline and fat injection [353]. The short-term analysis from the RCT does not give information about the effect of repeated injections.

A recent SR of 26 studies with 12 months follow-up showed objective success rates using urodynamics, 24-h pad tests, cough tests and voiding diaries ranging from 25.4% to 73.3%. A SR of 23 studies using Macroplastique© including 958 patients showed 75% improvement and 43% dry patients at less than 6 months but 64% improvements and 36% cures at more than 18 months [349]. A review of 514 elderly women with SUI treated with various agents showed a reduced pad weight in 73% at one year follow-up independently of the material injected [354]. Proximal urethral injection showed better outcome than mid-urethral injections [355]. Intra-urethral injections or peri-urethral injections produce similar outcomes, although the latter is associated with a higher risk of temporary urinary retention [347]. One study treated patients who had received radiotherapy with injection of Bulkamid© and reported around 25% cure at short term follow-up [356].

Bulking agent injection is safe, the most frequent adverse event being UTI. However, autologous fat or hyaluronic acid should not be used due to the risk of fatal embolism and local abscess formation, respectively [347, 352].

Comparison with open surgery
Two RCTs compared collagen injection to conventional surgery for SUI (autologous sling vs. silicon particles and collagen vs. other surgical procedures/bulking agents). The studies reported greater efficacy but higher complication rates for open surgery. In comparison, collagen injections showed inferior efficacy but equivalent levels of satisfaction and fewer serious complications [53, 357].

Another trial found that a peri-urethral route of injection can carry a higher risk of urinary retention compared to a transurethral injection [358]. A recent small RCT found no difference in efficacy between mid-urethral and bladder neck injection of collagen [359].

4.3.1.5.3 Summary of evidence for bulking agents

Summary of evidence	**LE**
Peri-urethral injection of bulking agent may provide short-term improvement and cure (twelve months), in women with SUI.	1b
Bulking agents are less effective than colposuspension or autologous sling for cure of SUI.	1b
Autologous fat and hyaluronic acid as bulking agents have a higher risk of adverse events.	1a
Adverse effect rates are lower compared to open surgery.	2a
There is no evidence that one type of bulking agent is better than another type.	1b
The peri-urethral route of injection of bulking agents may be associated with a higher risk of urinary retention compared to the transurethral route.	2b

4.3.1.6 Recommendations for women with uncomplicated stress urinary incontinence

Recommendations	**Strength rating**
Offer a MUS to women with uncomplicated SUI	Strong
Inform women of the unique complications associated with each individual procedure.	Strong
Inform women who are being offered a single-incision sling that long-term efficacy remains uncertain.	Strong
Inform women undergoing colposuspension that there is a longer duration of surgery, hospital stay and recovery, as well as a high risk of development of pelvic organ prolapse and voiding dysfunction post-operatively.	Strong
Inform older women with SUI about the increased risks associated with surgery, including the lower probability of success.	Weak
Inform women that any vaginal surgery may have an impact on sexual function, which is generally positive.	Weak
Only offer new devices, for which there is no level 1 evidence base, as part of a structured research programme.	Strong
Only offer adjustable MUS as a primary surgical treatment for SUI as part of a structured research programme.	Strong
Offer bulking agents to women with SUI who request a low-risk procedure with the understanding that repeat injections are likely and long-term durability is not established.	Strong

MUS = mid-urethral sling; SUI = stress urinary incontinence.

*4.3.2 **Complicated stress urinary incontinence in women***
This section will address surgical treatment for women who have had previous surgery for SUI, which has failed, or those women who have undergone previous radiotherapy affecting the vaginal or urethral tissues. Neurogenic LUT dysfunction is reviewed by the EAU Guidelines on Neuro-Urology [2]. Women with associated genitourinary prolapse are included in this edition (see section 4.3.3).

4.3.2.1 Colposuspension or sling following failed surgery
There may be persistent or recurrent SUI, or the development of *de novo* UUI. This means that careful evaluation including urodynamics becomes an essential part of the work-up of these patients.

4.3.2.1.1 Question

In women who have had failed surgery for SUI, what is the effectiveness of any second-line operation, compared to any other second-line operation, in terms of cure or improvement of UI, QoL or adverse events?

4.3.2.1.2 Evidence

Most of the data on surgery for SUI refer to primary operations. Even when secondary procedures have been included, it is unusual for the outcomes in this subgroup to be separately reported. When they are, the numbers of patients is usually too small to allow meaningful comparisons.

The 4th International Consultation on Incontinence includes a review of this topic [1] up to 2008, and the subject has also been reviewed by Ashok [360] and Lovatsis *et al.* [361]. A further literature review has been carried out since that time by the Panel.

Cochrane reviews of individual operative techniques have not included separate evaluation of outcomes in women undergoing second-line surgery. However, there is a current protocol to address this issue [362]. Only one RCT was found (abstract only) comparing TVT to laparoscopic colposuspension in women with recurrent SUI. This small study found similar cure rates and adverse events in the short term for both procedures [363].

Post-hoc subgroup analysis of high-quality RCTs comparing one procedure to another have shown conflicting evidence of relative effectiveness [78, 335, 364, 365]. One large non-randomised comparative series suggested that cure rates after more than two previous operations were 0% for open colposuspension and 38% for fascial sling [366].

Several cohort studies have reported outcomes for TVT specifically for primary and secondary cases. Evidence on the effectiveness of second-line retropubic tapes conflicts with some series showing equivalent outcomes for primary and secondary cases [367, 368], whilst other research has shown inferior outcomes for secondary surgery [369, 370]. Other confounding variables make meaningful conclusions difficult.

Systematic review of older trials of open surgery for SUI suggest that the longer-term outcomes of redo open colposuspension may be poor compared to autologous fascial slings [371]. Successful results have been reported from mid-urethral slings after various types of primary surgery, while good outcomes are reported for both repeat TVT and for 'tightening' of TVT, but data are limited to small case series only.

Systematic meta-analysis of retropubic (TVT) vs. transobsturator (TOT) MUS in the treatment of recurrent SUI showed no difference in terms of patient-reported or objective cure/improvement after a mean follow-up of eighteen months. In one RCT no difference between Burch colposuspension and TVT could be observed in either patient-reported or objective cure/improvement rates [372].

A large cohort study (112 pts) of mid-urethral slings for recurrent SUI showed an overall subjective success rate (cured/improved) of 76.8% at 21 months with no significant differences between the retropubic and transobturator routes [373].

4.3.2.1.3 Summary of evidence for colposuspension or sling following failed surgery for stress urinary incontinence

Summary of evidence	**LE**
There is conflicting evidence whether prior surgery for SUI or prolapse results in inferior outcomes from repeat operations for SUI.	2
Most procedures will be less effective when used as a second-line procedure.	2
In women who have had more than two procedures for SUI, the results of open colposuspension are inferior to autologous fascial sling.	2
Tension-free vaginal tape (TVT) and TOT have similar outcomes in patients with recurrent SUI.	1a
Burch colposuspension has similar patient-reported or objective cure rates when compared to TVT.	1b

SUI = stress urinary incontinence; TOT = trans-obturator tape; TVT = tension-free vaginal tape.

4.3.2.2 External compression devices

External compression devices are still widely used in the treatment of recurrent SUI after the failure of previous surgery and if there is thought to be profound intrinsic failure of the sphincter mechanism, characterised by very low leak point pressures or low urethral closure pressures. This should be confirmed by urodynamic evaluation.

The two intracorporeal external urethral compression devices available are the adjustable compression therapy (ACT©) device and the artificial urinary sphincter (AUS). Using ultrasound or fluoroscopic guidance, the ACT© device is inserted by placement of two inflatable spherical balloons on either side of the bladder neck. The volume of each balloon can be adjusted through a subcutaneous port placed within the labia majora. More recently, an adjustable artificial urinary sphincter (Flowsecure™) has been introduced. It has the potential added benefit of 'conditional occlusion', enabling it to respond to rapid changes in intra-abdominal pressure.

4.3.2.2.1 Questions

- In women with SUI, does insertion of an external compressive device cure SUI, improve QoL or cause adverse outcomes?
- How do external compression devices compare to other surgical treatments for SUI?

4.3.2.2.2 Evidence

The major advantage of AUS over other anti-incontinence procedures is the perceived ability to be able to void normally [115]. However, voiding dysfunction is a known side effect, with a lack of data making it difficult to assess its importance. Because of significant differences in design between devices and in selection criteria between case series, results obtained with specific devices cannot be extrapolated generally to the use of adjustable devices. A recent consensus report has standardised the terminology used for reporting complications arising from implantation of materials into the pelvic floor region [20].

Artificial urinary sphincter (AUS)

A previous review of mechanical devices concluded that there was insufficient evidence to support the use of AUS in women [374].

There are a few case series in women, including four series (n = 611), with study populations ranging from 45 to 215 patients and follow-up ranging from one month to 25 years [375-378]. Case series have been confounded by varying selection criteria, especially the proportion of women who have neurological dysfunction or who have had previous surgery. Most patients achieved an improvement in SUI, with reported subjective cures in 59-88%. Common side effects included mechanical failure requiring revision (up to 42% at ten years) and explantation (5.9-15%). In a retrospective series of 215 women followed up for a mean of six years, the risk factors for failure were older age, previous Burch colposuspension and pelvic radiotherapy [378]. Peri-operative injury to the urethra, bladder or rectum was also a high-risk factor for explantation [376].

A newly introduced artificial sphincter using an adjustable balloon capacity through a self-sealing port, and stress responsive design, has been introduced to clinical use. A series of 100 patients reported 28% explantation at four years but the device has undergone redesign and more up-to-date evidence is awaited [379]. Early reports of laparoscopically implanted AUS do not have sufficient patient populations and/or sufficient follow-up to be able to draw any conclusions [380, 381].

Adjustable compression device (ACT©)

There are four case series (n = 349), with follow-up ranging from five to 84 months [382-385]. Reported outcome ranged from 47% objective cure to 100% subjective improvement. However, most patients required adjustment to achieve continence and 21% required explantation.

4.3.2.2.3 Summary of evidence for external compression devices

Summary of evidence	**LE**
Implantation of an artificial sphincter can improve or cure incontinence in women with SUI caused by sphincter insufficiency.	3
Implantation of the adjustable compression therapy (ACT©) device may improve complicated UI.	3
Complications, mechanical failure and device explantation often occur with both the artificial sphincter and the ACT©.	3
Explantation is more frequent in older women and among those who have had previous Burch colposuspension or pelvic radiotherapy.	3

4.3.2.3 Recommendations for complicated stress urinary incontinence

Recommendations	Strength rating
Management of complicated SUI should only be offered in expert** centres.	Weak
The choice of surgery for recurrent SUI should be based on careful evaluation of the individual patient including multichannel urodynamics and imaging as appropriate.	Weak
Inform women with recurrent SUI that the outcome of a surgical procedure, when used as a second-line treatment, is generally inferior to its use as a first-line treatment, both in terms of reduced efficacy and increased risk of complications.	Weak
Consider secondary synthetic sling, colposuspension or autologous sling as first options for women with complicated SUI.	Weak
Inform women receiving AUS or ACT© that although cure is possible, even in expert centres, there is a high risk of complications, mechanical failure or a need for explantation.	Weak

ACT© = Adjustable compression device; AUS = artificial urinary sphincter; SUI = stress urinary incontinence; UI = urinary incontinence.

*** Expert centres refers to the comments on surgeon volume in the introduction to the surgical chapter.*

*4.3.3 **Women with both stress urinary incontinence and pelvic organ prolapse***

There is a clear association between the presence of POP and SUI. Although the subject of prolapse is not part of the remit of these Guidelines, the extent to which it impacts on the management of SUI will be addressed. The aim is to assess the options available to women who require surgery for POP and who have associated UI (either symptomatic or after reduction of prolapse), and to assess the value of prophylactic anti-incontinence surgery in women with no evidence of UI.

4.3.3.1 Questions

1. In women with POP and UI, does combined surgery for POP and SUI reduce the incidence of post-operative UI compared to POP surgery alone?
2. In continent women with POP, does combined surgery for POP and SUI reduce the incidence of post-operative *de novo* UI compared to POP surgery alone?
3. In women with POP and occult SUI, (i.e. seen only on prolapse reduction stress testing/ urodynamics), does combined surgery for POP and SUI reduce the incidence of post-operative UI compared to POP surgery alone?
4. In women with POP and OAB, does surgery for POP improve OAB symptoms?
5. In adults with POP, what is the reliability, the diagnostic accuracy and predictive value of a prolapse reduction test to identify patients at risk from *de novo* SUI following prolapse repair?

4.3.3.2 Evidence

A Cochrane review in 2013 included sixteen trials concerning bladder function after surgery for pelvic organ prolapse [386]. After prolapse surgery 434 of 2,125 women (20.4%) reported new subjective SUI, in sixteen trials. New voiding dysfunction was reported in 109 of 1,209 (9%) women, in twelve trials. A recent SR and metanalysis assessing prolapse surgery with or without stress incontinence surgery found that combination surgery reduces the risk of post-operative SUI, but short-term voiding difficulties and adverse events were more frequent after combination with a MUS [387].

1. In women with POP does combined surgery for POP and SUI reduce the incidence of post operative UI compared to POP surgery alone?

In summary, it is difficult to generalise the results of trials using very different procedures to treat both POP and UI. It seems that with a combined procedure the rate of SUI post-operatively is lower. Studies using mid-urethral slings have generally shown more significant differences in UI outcomes with combined procedures than when other types of anti-incontinence procedure have been used. Individual patient characteristics may play the most important role in shaping treatment decisions. It must be taken into account that, although more women may be dry after combined surgery, the risks of repeat surgery, should it become necessary, may outweigh the potential benefits.

There are two well-designed RCTs relating to the prevalence of post-operative SUI in women (continent or incontinent) who underwent prolapse surgery with and without an anti-incontinence procedure. Both of these trials involved women with POP who did not complain of symptoms of SUI regardless of objective findings.

One trial compared abdominal sacrocolpopexy with and without Burch colposuspension [363], the other compared vaginal repair with and without a mid-urethral sling [364]. In both trials addition of anti-

incontinence surgery reduced the risk of SUI at twelve months. In one trial there was a higher rate of adverse events reported in the combined surgery group [364]. This was also the finding of the Cochrane review and meta-analysis.

The most recent RCT by van der Ploeg including 7 trials found that significantly more women in the combined therapy group reported the absence of post-operative SUI [387]. They concluded that women undergoing POP surgery should be counselled about the possibility of combination surgery. They should know that there is strong evidence that post-operative SUI is less frequent after combining prolapse and anti-incontinence surgery relative to prolapse surgery only. However, the number needed to treat to prevent one SUI is probably considerable. The rate of adverse events is likely to be higher with combined surgery. Further evaluation was undertaken according to subgroups (with or without UI prior to surgery).

Women with POP and SUI

Three trials addressed post-operative SUI in patients who had SUI pre-operatively. Borstad *et al.*, in a multicentre trial, randomised women with POP and SUI to have a TVT at the time of prolapse repair or three months later, if they still had SUI (n = 53). One year after surgery there was no difference between the groups regarding continence; however, 44% of the women without initial TVT never required surgery and 29% were dry [388].

In contrast, Costantini *et al.* followed-up women with POP and SUI randomised to abdominal POP repair with or without Burch colposuspension (after a median of 97 months), finding that additional SUI surgery did not improve outcome [389]. On the contrary, a higher number of patients had *de novo* storage symptoms when a Burch colposuspension was performed.

The most recent RCT by van der Ploeg *et al.* found that more women in the combined therapy group reported the absence of UI (62% vs. 30%) and SUI (78% vs. 39%) [390]. Seventeen percent of women undergoing POP surgery alone required an additional MUS. Severe complications were more common in the MUS group 16% vs. POP surgery only 6%.

2. Women with POP asymptomatic for SUI

A pooled anlaysis of all studies (5) in continent women shows a reduction in both objective and subjective post-operative SUI after combined surgery with a reduced need for subsequent anti-incontinence surgery [387]. The number needed to treat (NNT) was six to prevent one woman developing *de novo* subjective SUI after POP repair, and 20 to prevent one woman undergoing an additional MUS.

3. Women with POP and occult SUI

A recent RCT by van der Ploeg *et al* found adressing occult incontinence found that women with occult SUI had a higher risk of reporting SUI after POP surgery than women without occult SUI [391]. Thirteen percent of women undergoing POP surgery aloneneeded an additional MUS. This is in line with the outcomes reported in the earlier SR. The NNT to prevent one woman with occult SUI from developing *de novo* subjective SUI after POP repair was three [387].

4. Women with POP and OAB

There are three case series evaluating patients with concomitant OAB and pelvic organ prolapse which assess incontinence/OAB symptom scores post-surgical repair. Costantini *et al.* assessed the effect of posterior repair on OAB/DO and reported a 70-75% improvement rate in both parameters along with a 93% anatomic success rate [392]. Kummeling *et al.* assessed the effect of a modified laparoscopic sacrocolpopexy on urodynamic parameters and reported an improvement with no evidence to support a concomitant prophylactic colposuspension [393]. Lee *et al.* assessed the value of pre-operative urodynamic study and bladder outlet obstruction index (BOOI) in predicting the degree of OAB symptoms post anterior prolapse repair. They reported a significant correlation between low pre-operative BOOI and improvement in OAB symptom scores post-operative [394].

5. Prolapse reduction stress test (PRST)

Data concerning PRST were made available from the CARE trial, where significant differences were noted in the detection of urodynamic stress incontinence with prolapse reduction among the various methods studied, ranging from 6% (pessary) to 30% (speculum). Manual, swab and forceps showed detection rates of 16%, 20% and 21%, respectively [395]. In the study by Duecy, about one third of women were diagnosed with occult SUI using a pessary while two thirds were diagnosed with manual reduction of the prolapse [396]. In a further study occult SUI was only detected by a pessary test in 19% of patients, not by urodynamics, history or clinical examination [397].

4.3.3.3 Summary of evidence for women with both stress urinary incontinence and pelvic organ prolapse

Summary of evidence	LE
Women with pelvic organ prolapse and urinary incontinence	
Surgery for pelvic organ prolapse (POP) + SUI shows a higher rate of cure of UI in the short term than POP surgery alone.	1a
There is conflicting evidence on the relative long-term benefit of surgery for POP + SUI vs. POP surgery alone.	1a
Combined surgery for POP + SUI carries a higher risk of adverse events than POP surgery alone.	1a
Continent women with pelvic organ prolapse	
Are at risk of developing UI post-operatively.	1a
The addition of a prophylactic anti-incontinence procedure reduces the risk of post-operative UI.	1a
The addition of a prophylactic anti-incontinence procedure increases the risk of adverse events.	1a
Women with pelvic organ prolapse and overactive bladder	
There is some low-level inconsistent evidence to suggest that surgical repair of POP can improve symptoms of overactive bladder.	2

4.3.3.4 Recommendations for women with both stress urinary incontinence and pelvic organ prolapse

Recommendations for women requiring surgery for bothersome pelvic organ prolapse who have symptomatic or unmasked SUI	Strength rating
Offer simultaneous surgery for pelvic organ prolapse and SUI.	Strong
Inform women of the increased risk of adverse events with combined surgery compared to prolapse surgery alone.	Strong
Recommendations for women requiring surgery for bothersome pelvic organ prolapse who do not have symptomatic or unmasked SUI	
Inform women that there is a risk of developing *de novo* SUI after prolapse surgery.	Strong
Warn women that the benefit of surgery for SUI may be outweighed by the increased risk of adverse events with combined surgery compared to prolapse surgery alone.	Strong

POP = pelvic organ prolapse; SUI = stress urinary incontinence; UI = urinary incontinence.

*4.3.4 **Urethral diverticulum***

A female urethral diverticulum is a sac-like protrusion made up by the entire urethral wall or only by the urethral mucosa situated between the periurethral tissues and the anterior vaginal wall. Urethral diverticula give rise to a variety of symptoms that include pain, urgency, frequency, recurrent UTIs, vaginal discharge, dyspareunia, voiding difficulties or urinary incontinence.

4.3.4.1 Question

In a woman with the clinical suspicion of having a urethral diverticulum, what is the best test to confirm the diagnosis?

4.3.4.2 Evidence

No robust diagnostic accuracy studies address this question. However, a case series of 27 patients concluded that endoluminal (vaginal or rectal) MRI has better diagnostic accuracy than voiding cystourethrography (VCUG) [398]. In a case series of 60 subjects Pathi, *et al.* reported that the sensitivity, specificity, positive predictive value and negative predictive value of MRI is 100%, 83%, 92% and 100%, respectively [399]. Dwarkasing *et al.* also reports 100% specificity and sensitivity of MRI in a case series of 60 patients [400]. However, in a case series of 41 patients, a study reported 25% discrepancy between MRI and surgical findings [401].

4.3.4.3 Question

In a woman who has a bothersome urethral diverticulum, what is the relative effectiveness of available surgical treatments?

4.3.4.4 Surgical treatment

No RCTs were found. Surgical removal is the most commonly reported treatment in contemporary case series. However, recurrence may occur; Han *et al.* found a recurrence rate of 33% in U-shaped and of 60% in circumferential diverticulum within one year [402], Ingber *et al.* found a 10.7% recurrence rate in 122 women

undergoing diverticulectomy, with a higher risk of recurrence in those with proximal or multiple diverticula or after previous pelvic surgery [403]. SUI may occur in up to 20% of women after diverticulectomy, requiring additional correction [404-407]. *De novo* SUI seems to be more common in proximal and in large size (> 30 mm) diverticula.

Diverticula may undergo neoplastic alterations (6%) including invasive adenocarcinomas [408].

4.3.4.5 Summary of evidence and recommendation for urethral diverticulum

Summary of evidence	LE
Magnetic resonance imaging has good sensitivity and specificity for the diagnosis of urethral diverticula; however, there is a risk of misdiagnosis and missing potential intraluminal neoplastic change.	3
Surgical removal of symptomatic urethral diverticula provides good long-term results; however, women should be counselled of the risk of recurrence and de novo SUI.	3

Recommendations	Strength rating
Symptomatic urethral diverticula should be completely surgically removed.	Strong

SUI = stress urinary incontinence.

*4.3.5 **Men with stress urinary incontinence***

In men who fail conservative treatment (see chapter 4.1.3.3.5) other treatments can be considered.

4.3.5.1 Drug therapy

Three RCTs suggest an earlier recovery of continence in men receiving duloxetine either alone [409], or in addition to PFMT, for post prostate surgery SUI [410, 411].

4.3.5.1.1 Summary of evidence for drug therapy in men with stress urinary incontinence

Summary of evidence	LE
Duloxetine, either alone or combined with conservative treatment, can hasten recovery of continence but does not improve continence rate following prostate surgery, but can be associated with significant, albeit often transient, side effects.	1b

4.3.5.2 Bulking agents in men

Injection of bulking agents has been used to try and improve the coaptation of a damaged sphincter zone. Initial reports showed limited efficacy in treating incontinence following radical prostatectomy [412, 413].

4.3.5.2.1 Question

In men with post-prostatectomy incontinence or SUI, does injection of a urethral bulking agent cure SUI, improve QoL, or cause adverse outcomes?

4.3.5.2.2 Evidence

Most studies are case series with small sample sizes. Small cohort studies showed a lack of benefit using a number of different materials [414, 415]. However, polyacrylamide hydrogel resulted in limited improvement in QoL without curing the UI [414]. A Cochrane review on the surgical treatment of post-prostatectomy incontinence found only one study that fulfilled the inclusion criteria [416]. A prospective, randomised study compared the AUS to silicone particles (Macroplastique™) in 45 patients. Eighty-two per cent of patients receiving an AUS were continent compared to 46% receiving silicone particles. In patients with severe incontinence, outcome was significantly worse after silicone bulking injection.

4.3.5.2.3 Summary of evidence for bulking agents in men

Summary of evidence	LE
There is no evidence that bulking agents cure post-prostatectomy incontinence.	2a
There is weak evidence that bulking agents can offer temporary, short-term, improvement in QoL in men with post-prostatectomy incontinence.	3
There is no evidence that one bulking agent is superior to another.	3

QoL = quality of life

4.3.5.3 Fixed male sling

In addition to external compression devices and bulking agents, slings have been introduced to treat post-prostatectomy incontinence. Fixed slings are positioned under the urethra and fixed by a retro-pubic or transobturator approach. The tension is adjusted during the surgery and cannot be re-adjusted post-operatively.

For the restoration of continence by these male slings, two concepts are now being proposed:

- continence restoration by urethral compression (InVance®, I-stop TOMS©);
- continence restoration by repositioning the bulb of urethra (AdVance©) [417].

In principle, the AUS can be used for all degrees of post-prostatectomy incontinence, while male slings are advocated for mild-to-moderate UI. However, the definitions of mild and moderate UI are not clear. The definition of cure, used in most studies, was no pad use or one security pad per 24 hours. Some authors used a stricter criterion of less than 2 g urine loss in a 24-hour pad test [418].

4.3.5.3.1 Question

In men with post-prostatectomy SUI, does insertion of a fixed suburethral sling cure SUI, improve QoL, or cause adverse outcomes?

4.3.5.3.2 Evidence

Concerning the surgical treatment of post-prostatectomy incontinence, three recent literature reviews are available [419-421]. There are a large number of uncontrolled case series concerning men implanted with several types of slings [422, 423].

For the repositioning sling (AdVance©), the benefit after a mean follow-up of three years has been published on 136 patients [424]. Earlier data were available from other cohort studies, totalling at least 614 patients with a mean follow-up of between three months and three years. Subjective cure rates for the device vary between 8.6% and 73.7%, with a mean of 49.5%. Pelvic radiotherapy was a negative prognostic factor [422]. Post-operative voiding dysfunction occurred in 5.7-1.3%, while erosions and chronic pain were uncommon (0-0.4%) [418, 424-426]. The overall failure rate was about 20%.

The previously available 'InVance®' device has now been removed from the market in some countries.

The strategy of intraoperative placement of an autologous vas deferens sling below the vesico-urethral anastomosis during robotic-assisted radical prostatectomy (RARP) has been explored with the intention to improve early return of continence. Two RCTs [427, 428] showed an advantage of sling vs. no sling at one month follow-up, and another study [429] showed an advantage of a 6-branch vs. a 2-branch sling at one month follow-up. However, a larger RCT [n = 195] showed that continence rate and near-continence rate were similar at six months with 66 vs. 65% and 88 vs. 87%, respectively [430].

4.3.5.3.3 Summary of evidence for fixed male sling

Summary of evidence	LE
There is limited short-term evidence that fixed male slings cure or improve post-prostatectomy incontinence in patients with mild-to-moderate incontinence.	3
There is no evidence that intraoperative placement of an autologous sling during RARP improves return of continence at 6 months.	1b
Men with severe incontinence, previous radiotherapy or urethral stricture surgery may have less benefit from fixed male slings.	3
There is no evidence that one type of male sling is better than another.	3

RARP = robotic assisted radical prostatectomy.

4.3.5.4 Adjustable slings in males

Adjustability in male sling surgery attempts to adjust the tension of the sling post-operatively. Three main systems have been used in men: the Remeex® system, the Argus® system and the ATOMS® system.

4.3.5.4.1 Question

In men with post-prostatectomy incontinence or SUI, does insertion of an adjustable suburethral sling cure or improve SUI, improve QoL, or cause adverse outcomes?

4.3.5.4.2 Evidence

There are no RCTs. Most studies consist of prospective or retrospective case series, with variable follow-up and different definitions of success. Some have been published only as conference abstracts. For the Remeex® system, only two abstracts, with conflicting findings, have been published. One study followed nineteen patients for nearly seven years and reported 70% success, with no explants, infections or erosions. The second study followed fourteen patients for 25 months. Only 36% of patients were satisfied and multiple re-adjustments were needed. Mechanical failure was reported in 21% [431].

Argus® system

Data on the Argus® system has been reported for 404 men, but only four series have reported on more than 50 patients [432, 433], with the longest follow-up being 2.4 years. Success rates varied between 17% and 91.6%, with a mean of 57.6% predominantly reporting a subjective cure. The number of implants requiring re-adjustment was reported as between 22.9% and 41.5% [433]. Infection of the device occurred in 5.4-8% [432]. Erosions were reported in 5-10% [434]. Urethral perforations occurred in 2.7-16% [432]. Pain at the implant site was usually only temporary, but chronic pain has been reported [432, 434]. These complications resulted in explantation rates of 10-15% [433].

The ATOMS® system consists of a mesh implant with an integrated adjustable cushion, which uses a titanium port left in the subcutaneous tissue of the lower abdomen or scrotum for adjustment of cushion volume. Initial reports show objective cure rates of 60.5% and improvement rates of 23.7% but with the need for up to nine post-operative adjustments [435, 436].

4.3.5.4.3 Summary of evidence for adjustable slings in males

Summary of evidence	**LE**
There is limited evidence that adjustable male slings can cure or improve SUI in men.	3
There is limited evidence that early explantation rates are high.	3
There is no evidence that adjustability offers additional benefit over other types of sling.	3

SUI = stress urinary incontinence.

4.3.5.5 Compression devices in males

External compression devices can be divided into two types: circumferential and non-circumferential compression of the urethral lumen [419]. The artificial urinary sphincter (AUS) is the standard treatment for moderate-to-severe male SUI. Most data available on the efficacy and adverse effects of AUS implantation are from older retrospective cohort studies with RCTs not performed due to the lack of a comparator. Men considering insertion of an AUS should understand that if the ability of an individual to operate the pump is uncertain, it may not be appropriate to implant an AUS. There are several recognised complications of AUS implantation, e.g. mechanical dysfunction, urethral constriction by fibrous tissue, erosion and infection. The non-circumferential compression devices consist of two balloons placed close to the vesico-urethral anastomotic site. The balloons can be filled and their volume can be adjusted post-operatively through an intra-scrotal port. Men who develop cognitive impairment or lose manual dexterity will have difficulty operating an AUS.

4.3.5.5.1 Question

In men with post-prostatectomy SUI, does insertion of an external compression device cure SUI, improve QoL, or cause adverse outcomes?

4.3.5.5.2 Evidence

Artificial urinary sphincter

Although the AUS is considered to be the standard treatment for men with SUI, there are three SRs [416, 421, 437] presenting limited evidence, of generally poor quality, except for one RCT comparing AUS with bulking

agents [412]. A continence rate of about 80% can be expected, while this may be lower in men who have undergone pelvic radiotherapy [419].

Trigo Rocha *et al.* published a prospective cohort study on 40 patients with a mean follow-up of 53 months, showing that from all urodynamic parameters only low bladder compliance had a negative impact on the outcome [438]. Another retrospective study showed that no urodynamic factors adversely altered the outcome of AUS implantation [439].

The transcorporeal technique of placement can be used for repeat surgery but evidence of effectiveness is lacking [440]. The dual-cuff placement was introduced to treat patients who remained incontinent with a single 4 cm cuff in place. However, it has not improved control of UI, while the availability of a 3.5 cm cuff may have eliminated the need for a dual cuff [441, 442]. Patients who experienced complete continence after AUS implantation had a higher erosion risk [443]. One small series reported results of AUS implantation after failure of previous AdVance© sling, showing no difference in efficacy between secondary and primary implantation [444].

Non-circumferential compression device (ProAct®)

There have been trials to treat post-prostatectomy SUI by insertion of a device consisting of balloons with adjustable volume external to the proximal bulbar urethra. A prospective cohort study (n = 128) described the functional outcome as 'good' in 68%, while 18% of the devices had to be explanted [445]. A subgroup of radiotherapy patients only had 46% success and a higher percentage of urethral erosions.

A quasi-randomised trial comparing a non-circumferential compression device (ProAct®) with bone-anchored male slings found that both types of device resulted in similar improvement of SUI (68% vs. 65%, respectively) [446]. Other prospective series have shown that adverse events were frequent, leading to an explantation rate of 11-58% [421, 447-450]. A questionnaire study showed that 50% of patients were still bothered significantly by persistent incontinence [451]. Other designs of artificial sphincter remain the subject of ongoing evaluation though they may have been introduced onto the market.

4.3.5.5.3 Summary of evidence for compression devices in males

Summary of evidence	LE
There is evidence that primary AUS implantation is effective for cure of SUI in men.	2b
Long-term failure rate for AUS is high although device replacement can be performed.	3
There are conflicting data on whether previous pelvic radiotherapy affects the outcome of AUS implantation.	3
The usefulness of tandem-cuff placement is uncertain.	3
There is insufficient evidence to state whether one surgical approach for cuff placement is superior to another.	3
Very limited short-term evidence suggests that the non-circumferential compression device (ProACT®) is effective for treatment of post-prostatectomy SUI.	3
The non-circumferential compression device (ProACT®) is associated with a high failure and complication rate leading to frequent explantation.	3
The rate of explantation of the AUS because of infection or erosion remains high (up to 24% in some series).	3
Mechanical failure is common with the AUS.	3
Revision and re-implantation of AUS is possible after previous explantation or for mechanical failure.	3

AUS = artificial urinary sphincter; SUI = stress urinary incontinence.

4.3.5.6 Recommendations for men with stress urinary incontinence

Recommendations	Strength rating
Offer duloxetine only to hasten recovery of continence after prostate surgery but inform the patient about the possible adverse events and that its use is off label for this indication in most European countries.	Weak
Only offer bulking agents to men with mild post-prostatectomy incontinence who desire temporary relief of incontinence symptoms.	Weak
Do not offer bulking agents to men with severe post-prostatectomy incontinence.	Weak
Offer fixed slings to men with mild-to-moderate* post-prostatectomy incontinence.	Weak

Warn men that severe incontinence, prior pelvic radiotherapy or urethral stricture surgery, may worsen the outcome of fixed male sling surgery.	Weak
Offer AUS to men with moderate-to-severe post-prostatectomy incontinence.	Weak
Implantation of AUS or ProACT© for men should only be offered in expert centres.	Weak
Warn men receiving AUS or ProACT© that, although cure can be achieved, even in expert centres, there is a high risk of complications, mechanical failure or a need for explantation.	Weak
Do not offer non-circumferential compression device (ProACT©) to men who have had pelvic radiotherapy.	Weak

** The terms "mild" and "moderate" post-prostatectomy incontinence remain undefined.*
ACT© = artificial compression device; AUS = artificial urinary sphincter.

*4.3.6 **Surgical interventions for refractory detrusor-overactivity***

4.3.6.1 Bladder wall injection of botulinum toxin A

Onabotulinum toxin A (onabotA; BOTOX®) 100 U dissolved in 10 mL of saline and injected in 20 points of the bladder wall above the trigone (0.5 mL per injection site) is licenced in Europe to treat OAB with persistent or refractory UUI in adults of both genders, despite the small number of males included in the registration trials [452, 453]. Surgeons must realise that other doses of onabotA and other formulations of botulinum toxin A, abobotulinum toxin A and incobotulinum toxin A, are not licensed for use in UUI. Doses for onabotA are not transposable to the other brands of botulinum toxin A. The continued efficacy of repeat injections is the rule but discontinuation rate may be high. The most important adverse events related to onabotA 100 U injection detected in the regulatory trials were UTI and an increase in PVR that may require clean intermittent catheterisation [454].

4.3.6.1.1 Question

In adults with UUI, is bladder wall injection of onabotA better than no treatment for cure or improvement?

4.3.6.1.2 Evidence

Following a dose ranging study in which the 100 U of onabotA was established as the ideal dose, two phase III trials randomised (1:1) 1,105 OAB incontinent patients whose symptoms were not adequately managed with anticholinergics to receive bladder wall injections of onabotA (100 U) or saline. At baseline, the population had on average more than five episodes of UUI, around twelve micturitions per day and a small PVR. At week twelve, in patients treated with onabotA, UUI episodes/day were halved and the number of micturitions/day reduced by more than two. A total of 22.9% of the patients in the onabotA arm were fully dry, against 6.5% in the saline arm [455].

Quality of life was substantially improved in the onabotA arm, as shown by the more than 60% of positive responses in the Treatment Benefit Scale questionnaire at week twelve, which was double the positive responses in the saline arm. Cohort studies have shown the effectiveness of bladder wall injections of onabotA in the elderly and frail elderly [456], though the success rate might be lower and the PVR (> 150 mL) higher in this group.

The median time to request re-treatment in the pooled analysis of the two RCTs was 24 weeks [454, 455]. Follow-up over 3.5 years showed consistent or increasing duration of effect for each subsequent treatment, with a median of 7.5 months [457].

A recent RCT compared onabotA injection 100 U to solifenacin (with dose escalation or switch to trospium possible in the solifenacin group) and showed similar rates of improvement in UUI over the course of six months [458]. However, patients receiving onabotA were not only more likely to have cure of UUI (27% vs. 13%, p = 0.003), but also had higher rates of urinary retention during the initial two months (5% vs. 0%) and of UTIs (33% vs. 13%). Patients taking antimuscarinics were more likely to have dry mouth.

Identification of DO in urodynamics does not influence the outcome of onabotulinum toxin A injections in patients with UUI [61].

4.3.6.1.3 Summary of evidence and recommendations for bladder wall injection of botulinum toxin A

Summary of evidence	LE
A single treatment session of onabotulinum toxin A (100 U) injected in the bladder wall is more effective than placebo at curing and improving UUI and QoL.	1a
There is no evidence that repeated injections of onabotulinum toxin A have reduced efficacy.	3
There is a high risk of increased PVR when injecting elderly frail patients.	3
The risk of bacteriuria after onabotulinum toxin A (100 U) injection is high but the clinical significance of this remains uncertain.	1b
Onabotulinum toxin A (100 U) is superior to solifenacin for cure of UUI, but rates of improvement were equivalent.	1b

Recommendations	Strength rating
Offer bladder wall injections of onabotulinum toxin A (100 U) to patients with UUI refractory to conservative therapy (such as PFMT and/or drug treatment).	Strong
Warn patients of the limited duration of response, risk of UTI and the possible prolonged need to self-catheterise (ensure that they are willing and able to do so).	Strong

PFMT = pelvic floor muscle training PVR = post-void residual; QoL = quality of life; UUI = urgency urinary incontinence; UTI = urinary tract infection.

4.3.6.2 Sacral nerve stimulation (neuromodulation)

In the first stage of a two-stage implantation, an electrode is placed percutaneously under fluoroscopic control in the sacral foramen alongside a sacral nerve, usually S3. In earlier techniques, a temporary wire electrode was used. More recently, a permanent tined electrode has been used for a longer test phase. Patients, in whom selected symptoms of UUI are reduced by more than 50% during the test phase, are candidates for the full implant, including the pulse generator, and reported results only apply to this sub population.

4.3.6.2.1 Question

In adults suffering from refractory UUI, what is the clinical effectiveness of sacral nerve neuromodulation compared to alternative treatments?

4.3.6.2.2 Evidence

All randomised studies suffer from the limitation that assessors and patients were not blinded to the treatment allocation since all recruited subjects had to respond to a test phase before randomisation. A Cochrane review of the literature until March 2008 [459] identified three RCTs that investigated sacral nerve stimulation in patients with refractory UUI.

One study compared implantation to controls who stayed on medical treatment and received delayed implantation at six months. Fifty percent of the immediately implanted group had > 90% improvement in UUI at six months compared to 1.6% of the control group [460]. The other RCT [461] achieved similar results, although these patients had already been included in the first report [460]. However, Weil *et al.* [461] showed that the effect on generic QoL measured by the SF-36, was unclear as it differed between the groups in only one of the eight dimensions.

The results of seventeen case series of patients with UUI, who were treated early in the experience with sacral nerve stimulation, were reviewed [462]. After a follow-up duration of between one and three years, approximately 50% of patients with UUI demonstrated > 90% reduction in UI, 25% demonstrated 50-90% improvement, and another 25% demonstrated < 50% improvement. Two case series describing the outcome of sacral nerve neuromodulation, with a mean or median follow-up of at least four years [463, 464] reported continued success (> 50% improvement on original symptoms) in patients available for follow-up. Cure rates for UUI were 15% [464]. A RCT comparing a strategy of onabotulinum toxinA injection of 200 U, repeated as required, against a strategy of test and permanent sacral nerve neuromodulation [465] (ROSETTA trial) showed lower cure rates with SNM: at six months, 20% in the onabotulinumtoxinA group and 4% in the sacral neuromodulation group had complete resolution of UUI ($p < .001$). Forty-six percent in the onabotulinumtoxinA group and 26% in the sacral neuromodulation group had at least a 75% reduction in the number of episodes of UUI ($p < .001$). This 4% cure rate is also lower than the 6 months cure rate in another RCT of sacral neuromodulation vs. standard medical therapy which reported a 39% continence rate in the sacral neuromodulation group at 6 months; however, the mean (SD) baseline leaks per day (2.4 [± 1.7]) for the sacral

neuromodulation group in the study were lower than in the ROSETTA trial (5.3 [± 2.7]), reflecting a less severe population [466].

Adverse events occurred in 50% of implanted cases, with surgical revision necessary in 33-41% [463, 464]. In a subanalysis of the RCT, the outcomes of UUI patients, with or without pre-implant DO, were compared. Similar success rates were found in patients with or without urodynamic DO [467].

4.3.6.2.3 Summary of evidence and recommendation for sacral nerve stimulation

Summary of evidence	**LE**
Sacral nerve neuromodulation is more effective than continuation of failed conservative treatment for cure of UUI, but no sham controls have been used.	1b
Sacral nerve neuromodulation is not more effective than OnabotulinumA toxin 200 U injection at 6 months.	1b
In those patients who have been implanted, at long-term, 50% improvement of UUI is maintained in at least 50% of patients and 15% may remain cured.	3
The use of tined, permanent electrodes in a staged approach results in more patients receiving the final implant than occurs with temporary test stimulation.	4

Recommendations	**Strength rating**
Offer sacral nerve modulation to patients who have UUI refractory to antimuscarinic therapy.	Strong

UUI = urgency urinary incontinence.

4.3.6.3 Cystoplasty/urinary diversion

4.3.6.3.1 Augmentation cystoplasty

In augmentation cystoplasty (also known as clam cystoplasty), a detubularised segment of bowel is inserted into the bivalved bladder wall. The distal ileum is the bowel segment most often used but any bowel segment can be used if it has the appropriate mesenteric length. One study did not find any difference between bivalving the bladder in the sagittal or in the coronal plane [468, 469]. The procedure can be done, with equal success by open or robot techniques, although the robotic consumes considerably more operative time [470].

There are no RCTs comparing bladder augmentation to other treatments for patients with UUI. Most often, bladder augmentation is used to correct neurogenic DO or small-capacity, low-compliant, bladders caused by fibrosis, chronic infection such as tuberculosis, radiation or chronic inflammation from interstitial cystitis.

The largest case series of bladder augmentation in a mixed population of idiopathic and neurogenic UUI included 51 women [471]. At an average follow-up of 74.5 months, only 53% were continent and satisfied with the surgery, whereas 25% had occasional leaks and 18% continued to have disabling UUI. It seems that the results for patients with idiopathic DO (58%) appeared to be less satisfactory than for patients with neurogenic UUI (90%).

Adverse effects were common and have been summarised in a review over five to seventeen years of more than 267 cases, 61 of whom had non-neurogenic UUI [472]. In addition, many patients may require clean intermittent self-catheterisation to obtain adequate bladder emptying (Table 3). It is unclear if mucolytic agents will reduce mucus accumulation. The only RCT that was identified comparing various mucolytic agents did not find significant benefits with the use of N-acetylcysteine, aspirin, or ranitidine. In one small study (n = 40), the use of subcutaneous octreotide immediately before, and for 15 days after surgery was reported to yield significant reductions in mucus production, the need for bladder irrigation to clear blockages, and the mean duration of hospital stay [473]

Depending on the relative costs of Onabotulinum Toxin A and augmentation cytoplasty, the latter can be cost effective within five years if the complication rate is low and duraton of effect of Onabotulinum Toxin A < 5 months [474].

Table 3: Complications of bladder augmentation

Short-term complications	**Affected patients (%)**
Bowel obstruction	2
Infection	1.5
Thromboembolism	1
Bleeding	0.75
Fistula	0.4
Long-term complications	**Affected patients (%)**
Clean intermittent self-catheterisation	38
Urinary tract infection	70% asymptomatic 20% symptomatic
Urinary tract stones	13
Metabolic disturbance	16
Deterioration in renal function	2
Bladder perforation	0.75
Change in bowel symptoms	25

4.3.6.3.2 Detrusor myectomy (bladder auto-augmentation)

Detrusor myectomy aims to increase bladder capacity and reduce storage pressures by incising or excising a portion of the detrusor muscle, to create a bladder mucosal 'bulge' or pseudo-diverticulum. It was initially described as an alternative to bladder augmentation in children [475].

Two case series [476, 477] in adult patients with idiopathic and neurogenic bladder dysfunction, demonstrated poor long-term results caused by fibrosis of the pseudo-diverticulum. This technique is rarely, if ever, used nowadays.

4.3.6.3.3 Urinary diversion

Urinary diversion remains a reconstructive option for patients with intractable incontinence after multiple pelvic procedures, radiotherapy or pelvic pathology leading to irreversible sphincteric incompetence or fistula formation. These patients may be offered irreversible urinary diversion surgery. Options include ileal conduit urinary diversion, orthotopic neobladder and heterotopic neobladder with Mitrofanoff continent catheterisable conduit. There is insufficient evidence to comment on which procedure leads to the most improved QoL.

A small study compared ileal with colonic conduits and concluded that there were no differences in the relative risks of UUT infection and uretero-intestinal stenosis. However, there are no studies that have specifically examined these techniques in the treatment of intractable UUI [468]. Therefore, careful consideration on which operation is undertaken will depend on patient factors and informed patient choice.

4.3.6.3.4 Summary of evidence and recommendations for cystoplasty/urinary diversion

Summary of evidence	**LE**
There is limited evidence on the effectiveness of augmentation cystoplasty and urinary diversion in treatment of idiopathic DO.	3
Augmentation cystoplasty and urinary diversion are associated with high risks of short-term and long-term severe complications.	3
The need to perform clean intermittent self-catheterisation following augmentation cystoplasty is very common.	3
There is no evidence comparing the efficacy or adverse effects of augmentation cystoplasty with urinary diversion.	3
Detrusor myectomy is ineffective in adults with UI.	3

Recommendations	Strength rating
Offer augmentation cystoplasty to patients with UI who have failed all other treatment options.	Weak
Inform patients undergoing augmentation cystoplasty of the high risk of having to perform clean intermittent self-catheterisation (ensure they are willing and able to do so) and that they need lifelong surveillance.	Weak
Do not offer detrusor myectomy as a treatment for UI.	Weak
Only offer urinary diversion to patients who have failed less invasive therapies for the treatment of UI and who will accept a stoma and have been warned about the possible small risk of malignancy.	Weak

DO = detrusor overactivity; UI = urinary incontinence.

*4.3.7 **Surgery in patients with mixed urinary incontinence***

4.3.7.1 Question

In adults with MUI, is the outcome of surgery different to that obtained with the same treatment in patients with either pure SUI or pure UUI?

4.3.7.2 Evidence

Many RCTs include both patients with pure SUI or pure UUI and patients with MUI. However, very few RCTs report separate outcomes for MUI and pure UI groups.

Post-hoc analysis of the SISTER trial showed that in women undergoing either autologous fascial sling or Burch colposuspension, the outcomes were poorer for women with a concomitant complaint of pre-operative urgency [335]. A similar *post-hoc* review of another RCT comparing transobturator and retropubic mid-urethral slings showed that the greater the severity of pre-operative urgency, the more likely that treatment would fail [78]. However, an earlier study had found that surgery provided similar outcomes, whether or not urgency was present prior to surgery (this study included only a few patients with urodynamic DO). Another RCT with 93 patients with MUI showed a statistical improvement in continence and QOL in the group that had TVT and Botox rather than with either treatment alone [478].

Case series tend to show poorer results in patients with MUI compared with those with pure SUI. In a case series of 192 women undergoing mid-urethral sling insertion, overall satisfaction rates were lower for women with mixed symptoms and detrusor overactivity on pre-operative urodynamics compared to those with pure SUI and normal urodynamics (75% vs. 98%, respectively) [479]. A comparison of two parallel cohorts of patients undergoing surgery for SUI, with and without DO, found inferior outcomes in women with MUI [480].

One cohort of 450 women, showed that in urgency-predominant MUI, the success rate fell to 52% compared to 80% in stress-predominant MUI [481]. In a study with 1,113 women treated with transvaginal obturator tape, SUI was cured equally in stress-predominant MUI or urgency-predominant MUI. However, women with stress-predominant MUI were found to have significantly better overall outcomes than women with urgency predominant MUI [482].

In a prospective, multicentre, comparative trial, 42 women who had a TVT for mixed UI had a greater improvement in urgency and QOL scores than 90 women who had a TOT. There were no significant differences in the cure and satisfaction rates between the two groups [483].

Overall, the outcome for women with pre-existing urgency incontinence remains uncertain.

4.3.7.3 Summary of evidence and recommendations for surgery in patients with mixed urinary incontinence

Summary of evidence	LE
Women with MUI are less likely to be cured of their UI by SUI surgery than women with SUI alone.	1b
The response of pre-existing urgency symptoms to SUI surgery is unpredictable.	3

Recommendations	Strength rating
Treat the most bothersome symptom first in patients with MUI.	Weak
Warn women that surgery for MUI is less likely to be successful than surgery for SUI alone.	Strong
Inform women with MUI that one single treatment may not cure UI; it may be necessary to treat other components of the incontinence problem as well as the most bothersome symptom.	Strong

MUI = mixed urinary incontinence; SUI = stress urinary incontinence; UI = urinary incontinence.

4.3.7.4 Research priorities

Research trials should define accurately what is meant by 'mixed urinary incontinence'.
There is a need for well-designed trials comparing treatments in populations with MUI, and in which the type of MUI has been accurately defined.

*4.3.8 **Surgery for urinary incontinence in the elderly***

There are no RCTs comparing surgical treatment in older vs. younger women although subgroup analyses of some RCTs have included a comparison of older with younger cohorts.

A RCT of 537 women comparing retropubic to transobturator tapes, showed that cure rates decreased and failure increased with each decade over the age of 50 [333]. A RCT assessing risk factors for failure of TVT vs. TOT in 162 women found that age is a specific risk factor (adjusted OR 1.7 per decade) for recurrence at one year [334]. In a subanalysis of the SISTER trial cohort of 655 women at 2 years of follow-up, it was shown that elderly women were more likely to have a positive stress test at follow-up (OR 3.7, 95% CI: 1.7-7.97), are less likely to report objective or subjective improvement in stress and urgency UI, and are more likely to undergo re-treatment for SUI (OR 3.9, 95% CI: 1.3-11.48). There was no difference in time to normal post-operative voiding [335].

Another RCT compared immediate TVT vs. delayed TVT in older women, confirming significant efficacy for the women operated upon, but the cohort as a whole suffered higher complication rates, particularly bladder perforation (22%) and urinary retention (13%) [336].

A cohort study of 256 women undergoing inside-out TOT reported similar efficacy in older vs. younger women, but there was a higher risk of *de novo* urgency in older patients [330].

Cohort studies have shown the effectiveness of onabotulinum toxin A injections in the elderly and frail elderly [456, 484], although a comparison of cohort groups suggests that there is a lower success rate in the frail elderly and also a higher rate of increased PVR (> 150 mL) in this group.

4.3.8.1 Summary of evidence and recommendation for surgery for urinary incontinence in the elderly

Summary of evidence	LE
Older women benefit from surgical treatment for incontinence.	1
The risk of failure from surgical repair of SUI, or of suffering adverse events, appears to increase with age.	2
There is no evidence that any surgical procedure has greater efficacy or safety in older women than another procedure.	4

Recommendations	Strength rating
Inform older women with UI about the increased risks associated with surgery (including onabotA injection), together with the lower probability of benefit.	Weak

SUI = stress urinary incontinence; UI = urinary incontinence.

Figure 1: Management and treatment of women presenting with urinary incontinence

*Available evidence refers mainly to women

APPENDIX A: NON OBSTETRIC URINARY FISTULA

A.2 Introduction

The evidence relating to diagnosis and treatment of urinary fistulae is generally poor and this review inevitably relies largely on numerous case series and other consensus statements. In particular, the epidemiology, aetiology, diagnosis, treatment and prevention of non-obstetric fistulae have been described in detail during the recent International Consultations on Incontinence [485, 486]. Most non-obstetric fistulae are iatrogenic in origin, with causes including pelvic surgery (particularly hysterectomy for benign or malignant conditions, caesarean section and obstetric injuries). The risks during pelvic surgery increase relative to the complexity of the resection, the extent of primary disease and when there has been prior radiotherapy (especially for recurrent disease). When a fistula occurs following radiotherapy for primary treatment, this may be an indication of tumour recurrence.

A.3 Diagnosis of fistula

Clinical diagnosis

Leakage of urine is the hallmark sign of a fistula. The leakage is usually painless, may be intermittent if it is position dependent, or may be constant. Unfortunately, intra-operative diagnosis of a GU or GI injury is made in only about half of the cases that result in fistula [487].

The diagnosis of vesicovaginal fistula (VVF) usually requires clinical assessment often in combination with appropriate imaging or laboratory studies. Direct visual inspection, cystoscopy, retrograde bladder filling with a coloured fluid or placement of a tampon into the vagina to identify staining may facilitate the diagnosis of a VVF. A double-dye test to differentiate between a ureterovaginal and VVF may be useful in some cases [488]. Testing the creatinine level in either the extravasated fluid or the accumulated ascites and comparing this to the serum creatinine level will confirm urinary leakage.

Contrast-enhanced CT with late excretory phase reliably diagnoses urinary fistulae and provides information about ureteric integrity and the presence of associated urinoma. Magnetic resonance imaging, in particular with T2 weighting, also provides optimal diagnostic information regarding fistulae and may be preferred for urinary - intestinal fistulae [489].

A.4 Management of vesicovaginal fistula

A.3.1 ***Conservative management***

Before epithelialisation is complete an abnormal communication between viscera will tend to close spontaneously, provided that the natural outflow is unobstructed or if urine is diverted. Combining available data gives an overall spontaneous closure rate of 13% ± 23% [490], though this applies largely to small fistulae [486]. Hence, immediate management should be by urinary catheterisation or diversion.

A.3.2 ***Surgical management***

Timing of surgery

Findings from uncontrolled case series suggest no difference in success rates for early or delayed closure of VVF.

A.3.2.1 Surgical approaches

Vaginal procedures

There are two main types of closure techniques applied to the repair of urinary fistulae, the classical saucerisation/partial colpocleisis [491] and the more commonly used dissection and repair in layers or ‘flapsplitting’ technique [492]. There are no data comparing their outcomes.

Abdominal procedures

Repair by the abdominal route is indicated when high fistulae are fixed in the vault and are inaccessible through the vagina. A transvesical repair has the advantage of being entirely extraperitoneal. A simple transperitoneal repair is used less often although it is favoured by some using the laparoscopic approach. A combined transperitoneal and transvesical procedure is favoured by many urologists and is particularly useful for fistula repair following Caesarean section. There are no RCTs comparing abdominal and vaginal approaches. Results of secondary and subsequent repairs are not as good as primary repair [493].

A single RCT compared trimming of the fistula edge with no trimming [494]. There was no difference in success rates but failed repairs in trimmed cases ended up with larger recurrences than untrimmed cases, which were smaller.

Laparoscopic and Robotic

Very small series (single figures) have been reported using these techniques, but whilst laparoscopic repair is feasible with and without robotic assistance, it is not possible to compare outcomes with alternative surgical approaches.

Tissue Interposition

Tissue flaps are often added as an additional layer of repair during VVF surgery. Most commonly, such flaps are utilised in the setting of recurrence after a prior attempt at repair, for VVF related to previous radiotherapy (described later), ischemic or obstetrical fistulae, large fistulae, and finally those associated with a difficult or tenuous closure due to poor tissue quality. However, there is no high-level evidence that the use of such flaps improves outcomes for either complicated or uncomplicated VVF.

Post-operative management

There is no high-level evidence to support any particular practice in post-operative management but most reported series used catheter drainage for at least ten days and longer periods in radiation-associated fistulae (up to three weeks).

A.4 Management of radiation fistula

Modified surgical techniques are often required, and indeed, where the same techniques have been applied to both surgical and post-radiation fistulae, the results from the latter have been consistently poorer [495]. Due to the wide field abnormality surrounding many radiotherapy-associated fistulae, approaches include, on the one hand, permanent urinary and/or faecal diversion [496, 497] or alternatively preliminary urinary and faecal diversion, with later undiversion in selected cases following reconstruction. This may in some cases extend life perhaps inappropriately, and where life expectancy is deemed to be very short, ureteric occlusion might be more appropriate.

A.5 Management of ureteric fistula

General principles

Patients at higher risk of ureteric injury require experienced surgeons who can identify and protect the ureter and its blood supply to prevent injury and also recognise injury promptly when it occurs. Immediate repair of any intra-operative injury should be performed observing the principles of debridement, adequate blood supply and tension-free anastomosis with internal drainage using stents [490]. Delayed presentation of upper tract injury should be suspected in patients whose recovery after relevant abdominal or pelvic surgery is slower than expected, if there is any fluid leak, and if there is any unexpected dilatation of the pelvicalyceal system. Whilst there is no evidence to support the use of one surgical approach over another, there is consensus that repair should adhere to the standard principles of tissue repair and safe anastomosis, and be undertaken by an experienced team. Conservative management is possible with internal or external drainage, endoluminal management using nephrostomy and stenting where available, and early (< two weeks) or delayed (> three months) surgical repair when required [498]. Functional and anatomical imaging should be used to follow up patients after repair to guard against development of ureteric stricture and deterioration in renal function.

Ureterovaginal fistula

Ureterovaginal fistula occurring in the early post-operative phase predominantly after hysterectomy is the most frequent presentation of UUT fistulae in urological practice. An RCT in 3,141 women undergoing open or laparoscopic gynaecological surgery found that prophylactic insertion of ureteric stents made no difference to the low risk (1%) of ureteric injury [499].

Endoscopic management is sometimes possible [500] by retrograde stenting, percutaneous nephrostomy and antegrade stenting if there is pelvicalyceal dilatation, or ureteroscopic realignment [501].

If endoluminal techniques fail or result in secondary stricture, the abdominal approach to repair is standard and may require end-to-end anastomosis, re-implantation into the bladder using psoas hitch or Boari flap, or replacement with bowel segments with or without reconfiguration.

A.6 Management of urethrovaginal fistula

Aetiology

Whilst they are rare, most urethrovaginal fistulae in adults have an iatrogenic aetiology. Causes include surgical treatment of stress incontinence with bulking agents or synthetic slings, surgery for urethral diverticulum and genital reconstruction in adults. Irradiation and even conservative treatment of prolapse with pessaries can lead to the formation of fistulae.

A.6.1 ***Diagnosis***

Clinical vaginal examination, including the three swab test, is often sufficient to diagnose the presence of a urethrovaginal fistula. Urethroscopy and cystoscopy can be performed to assess the extent and location of the fistulae. In cases of difficult diagnosis, voiding cystourethrography (VCUG) or ultrasound can be useful. 3D MRI or CT scan is becoming utilised more widely to clarify anatomy [502, 503].

A.6.2 ***Surgical repair***

Choice of surgery will depend on the size, localisation and aetiology of the fistula and the amount of tissue loss. Principles of reconstruction include identifying the fistula, creation of a plane between vaginal wall and urethra, watertight closure of urethral wall, eventual interposition of tissue, and closure of the vaginal wall.

A.6.2.1 Vaginal approach

Goodwin described in his series that a vaginal approach yielded a success rate of 70% at first attempt and 92% at second attempt, but that an abdominal approach only leads to a successful closure in 58% of cases. A vaginal approach required less operating time, had less blood loss and a shorter hospitalisation time.

Most authors describe surgical principles that are identical to those of vesicovaginal fistula repair: primary closure rates of 53-95.4% have been described. Pushkar *et al.* described a series of 71 women, treated for urethrovaginal fistula. 90.1% of fistulae were closed at the first vaginal intervention. Additionally, 7.4% were closed during a second vaginal intervention. Despite successful closure, stress incontinence developed in 52%. The stress incontinent patients were treated with synthetic or autologous slings and nearly 60% became dry and an additional 32% improved. Urethral obstruction occurred in 5.6% and was managed by urethral dilation or urethrotomy [504].

Flaps and neourethra.

The simplest flap is a vaginal advancement flap to cover the urethral suture line. Labial tissue can be harvested as a pedicled skin flap. This labial skin can be used as a patch to cover the urethral defect, but can also be used to create a tubular neo-urethra [505, 506]. The construction of a neo-urethra has mostly been described in traumatic aetiologies. In some cases a transpubic approach has been used [507]. The numbers of patients reported are small and there are no data on the long-term outcome of fistula closure and continence rates. The underlying bulbocavernosus tissue can be incorporated in the pedicled flap and probably offers a better vascularisation and more bulking to the repair. This could allow a safer placement of a sling afterwards, in those cases where bothersome stress incontinence would occur post-operatively [508, 509].

Martius flap

While in obstetrical fistula repair it was not found to have any benefit, in a large retrospective study in 440 women the labial bulbocavernosus muscle/fat flap by Martius is still considered by some to be an important adjunctive measure in the treatment of genitourinary fistulae where additional bulking with well vascularised tissue is needed [510]. The series of non-obstetrical aetiology are small and all of them are retrospective. There are no prospective data, nor randomised studies [511]. The indications for Martius flap in the repair of all types of fistulae remain unclear.

Rectus muscle flap

Rectus abdominis muscle flaps have been described by some authors [512, 513].

A.6.2.2 Abdominal approach

A retropubic retrourethral technique has been described by Koriatim [514]. This approach allows a urethrovesical flap tube to be fashioned to form a continent neo-urethra.

A.7 Summary of evidence and recommendations for management of urethrovaginal fistula

Summary of evidence	**LE**
Spontaneous closure of surgical fistulae does occur, although it is not possible to establish the rate with any certainty.	3
There is no evidence that the timing of repair makes a difference to the chances of successful closure of a fistula.	3
There is no high-quality evidence of differing success rates for repair of vesicovaginal fistulae by vaginal, abdominal, transvesical and transperitoneal approaches.	3

A period of continuous bladder drainage is crucial to successful fistula repair but there is no high-level evidence to support one regime over another.	3
A variety of interpositional grafts can be used in either abdominal or vaginal procedures, although there is little evidence to support their use in any specific setting.	3
Post-radiation fistula	
Successful repair of irradiated fistulae requires prior urinary diversion and the use of non-irradiated tissues to effect repair.	3
Ureteric fistula	
Prophylactic ureteric stent insertion does not reduce risk of ureteric injury during gynaecological surgery.	2
Antegrade endoluminal distal ureteric occlusion combined with nephrostomy tube diversion often palliates urinary leakage due to malignant fistula in the terminal phase.	4
Urethrovaginal fistula	
Urethrovaginal fistula repair may be complicated by stress incontinence, urethral stricture and urethral shortening necessitating long-term follow-up.	3

Recommendations	Strength rating
General	
Surgeons undertaking complex pelvic surgery should be competent at identifying, preserving and repairing the ureter.	Weak
Do not routinely use ureteric stents as prophylaxis against injury during routine gynaecological surgery.	Weak
Suspect ureteric injury or fistula in patients following pelvic surgery if a fluid leak or pelvicalyceal dilatation occurs post-operatively, or if drainage fluid contains high levels of creatinine.	Weak
Suspect uretero-arterial fistula in patients presenting with haematuria with a history of relevant surgery.	Weak
Use three dimensional imaging techniques to diagnose and localise urinary fistulae.	Weak
Manage upper urinary tract fistulae by conservative or endoluminal technique where such expertise and facilities exists.	Weak
Surgical principles	
Surgeons involved in fistula surgery should have appropriate training, skills, and experience to select an appropriate procedure for each patient.	Weak
Attention should be given as appropriate to skin care, nutrition, rehabilitation, counselling and support prior to, and following, fistula repair.	Weak
If a vesicovaginal fistula is diagnosed within six weeks of surgery, consider indwelling catheterisation for a period of up to twelve weeks after the causative event.	Weak
Tailor the timing of fistula repair to the individual patient and surgeon requirements once any oedema, inflammation, tissue necrosis, or infection, are resolved.	Weak
Where concurrent ureteric re-implantation or augmentation cystoplasty are required, the abdominal approach is necessary.	Weak
Ensure that the bladder is continuously drained following fistula repair until healing is confirmed (expert opinion suggests: 10-14 days for simple and/or postsurgical fistulae; 14-21 days for complex and/or post-radiation fistulae).	Weak
Where urinary and/or faecal diversions are required, avoid using irradiated tissue for repair.	Weak
Use interposition grafts when repair of radiation associated fistulae is undertaken.	Weak
In patients with intractable UI from radiation-associated fistula, where life expectancy is very short, consider performing ureteric occlusion.	Weak
Repair persistent ureterovaginal fistula by an abdominal approach using open, laparoscopic or robotic techniques according to availability and competence.	Weak
Consider palliation by nephrostomy tube diversion and endoluminal distal ureteric occlusion for patients with ureteric fistula associated with advanced pelvic cancer and poor performance status.	Weak
Urethrovaginal fistulae should preferably be repaired by a vaginal approach.	Weak

UI = urinary incontinence

6. CONFLICT OF INTEREST

All members of the Urinary Incontinence Guidelines Panel have provided disclosure statements on all relationships that they have and that might be perceived to be a potential source of conflict of interest. This information is publically accessible through the European Association of Urology website: http://uroweb.org/guideline/.

This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

7. CITATION INFORMATION

The format in which to cite the EAU Guidelines will vary depending on the style guide of the journal in which the citation appears. Accordingly, the number of authors or whether, for instance, to include the publisher, location, or an ISBN number may vary.

The compilation of the complete Guidelines should be referenced as:
EAU Guidelines. Edn. presented at the EAU Annual Congress Amsterdam, 2020. ISBN 978-94-92671-07-3.

If a publisher and/or location is required, include:
EAU Guidelines Office, Arnhem, The Netherlands. http://uroweb.org/guidelines/compilations-of-all-guidelines/

References to individual guidelines should be structured in the following way:
Contributors' names. Title of resource. Publication type. ISBN. Publisher and publisher location, year.

TABLE OF CONTENTS PAGE

1. INTRODUCTION

1.1 Aim and objectives

The European Association of Urology (EAU) Neuro-Urology Guidelines aim to provide information for clinical practitioners on the incidence, definitions, diagnosis, therapy, and follow-up of neuro-urological disorders. These Guidelines reflect the current opinion of experts in this specific pathology and represent a state-of-the art reference for all clinicians, as of the publication date.

The terminology used and the diagnostic procedures advised throughout these Guidelines follow the recommendations for investigations of the lower urinary tract (LUT) as published by the International Continence Society (ICS) [1-3]. Readers are advised to consult other EAU Guidelines that may address different aspects of the topics discussed in this document.

It must be emphasised that clinical guidelines present the best evidence available to the experts but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The EAU Neuro-Urology Guidelines Panel consists of an international multidisciplinary group of neuro-urological experts. All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website: http://www.uroweb.org/guideline/neuro-urology/.

1.3 Available publications

A quick reference document, the Pocket Guidelines, is available in print and as an app for iOS and Android devices. These are abridged versions which may require consultation with the full text version. A guideline summary has also been published in European Urology [4]. All are available through the EAU website: http://www.uroweb.org/guideline/neurourology/.

1.4 Publication history

The EAU published the first Neuro-Urology Guidelines in 2003 with updates in 2008, 2014, and 2017. This 2020 document represents a limited update of the 2019 publication. The literature was assessed for all chapters.

1.5 Background

The function of the LUT is mainly storage and voiding of urine, which is regulated by the nervous system that coordinates the activity of the urinary bladder and bladder outlet. The part of the nervous system that regulates LUT function is disseminated from the peripheral nerves in the pelvis to highly specialised cortical areas. Any disturbance of the nervous system involved, can result in neuro-urological symptoms. The extent and location of the disturbance will determine the type of LUT dysfunction, which can be symptomatic or asymptomatic. Neuro-urological symptoms can cause a variety of long-term complications; the most significant being deterioration of renal function. Since symptoms and long-term complications do not correlate [5], it is important to identify patients with neuro-urological symptoms, and establish if they have a low or high risk of subsequent complications. The risk of developing upper urinary tract (UUT) damage and renal failure is much lower in patients with slowly progressive non-traumatic neurological disorders than in those with spinal cord injury or spina bifida [6]. In summary, treatment and intensity of follow-up examinations are based on the type of neuro-urological disorder and the underlying cause.

2. METHODS

2.1 Introduction

For the 2020 Neuro-Urology Guidelines, new and relevant evidence has been identified, collated and appraised through a structured assessment of the literature. A broad and comprehensive literature search, covering all sections of the Neuro-Urology Guidelines was performed. Databases searched included Medline, EMBASE, and the Cochrane Libraries, covering a time frame between May 31st 2018 and 1st April 2019. A total of 754 unique records were identified, retrieved and screened for relevance. A detailed search strategy is available online: http://uroweb.org/guideline/neuro-urology/?type=appendices-publications.

For each recommendation within the guidelines there is an accompanying online strength rating form, the bases of which is a modified GRADE methodology [7, 8]. Each strength rating form addresses a number of key elements namely:

1. the overall quality of the evidence which exists for the recommendation, references used in this text are graded according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [9];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact of patient values and preferences on the intervention;
6. the certainty of those patient values and preferences.

These key elements are the basis which panels use to define the strength rating of each recommendation. The strength of each recommendation is represented by the words 'strong' or 'weak' [10]. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and nature and variability of patient values and preferences.

Additional information can be found in the general Methodology section of this print, and online at the EAU website; http://www.uroweb.org/guideline/. A list of associations endorsing the EAU Guidelines can also be viewed online at the above address.

2.2 Review

Publications ensuing from panel-led systematic reviews have all been peer-reviewed. The 2015 Neuro-Urology Guidelines were subject to peer review prior to publication.

3. THE GUIDELINE

3.1 Epidemiology, aetiology and pathophysiology

*3.1.1 **Introduction***

Neuro-urological symptoms may be caused by a variety of diseases and events affecting the nervous system controlling the LUT. The resulting neuro-urological symptoms depend predominantly on the location and the extent of the neurological lesion. There are no exact figures on the overall prevalence of neuro-urological disorders in the general population, but data are available on the prevalence of the underlying conditions and the relative risk of these for the development of neuro-urological symptoms. It is important to note that the majority of the data shows a very wide range of prevalence/incidence. This reflects the variability in the cohort (e.g. early or late stage disease) and the frequently small sample sizes, resulting in a low level of evidence in most published data (summarised in Table 1).

Table 1: Epidemiology of Neuro-Urological Disorders

Suprapontine and pontine lesions and diseases		
Neurological Disease	**Frequency in General Population**	**Type and Frequency of Neuro-Urological Symptoms**
Cerebrovascular accident (Strokes)	450 cases/100,000/yr (Europe) [11], 10% of cardiovascular mortality.	Nocturia - overactive bladder (OAB) - urgency urinary incontinence (UUI) - detrusor overactivity (DO), other patterns less frequent [12]. 57-83% of neuro-urological symptoms at 1 month post-stroke, 71-80% spontaneous recovery at 6 months [13]. Persistence of urinary incontinence (UI) correlates with poor prognosis [14].
Dementias: Alzheimer's disease (80%), Vascular (10%), Other (10%).	6.4% of adults > 65 yrs [15].	OAB - UUI – DO 25% of incontinence in Alzheimer's disease, > 25% in other dementias: Lewy body, NPH, Binswanger, Nasu-Hakola, Pick Disease [16]. Incontinence 3 times more frequent in geriatric patients with dementia than without [17].
Parkinsonian syndrome (PS) Idiopathic Parkinson's disease (IPD): 75-80% of PS.	Second most prevalent neurodegenerative disease after Alzheimer's disease. Rising prevalence of IPD with age [18].	Urinary symptoms affect 50% at onset, with urgency and nocturia being the most common. Patients with urinary symptoms at presentation have worse disease progression in Parkinson's disease [19].
Non-IPD: Parkinson's-plus (18%): - Multiple system atrophy (MSA), - Progressive supranuclear palsy, - Corticobasal degeneration, - Dementia with Lewy bodies. Secondary Parkinson's (2%)	MSA is the most frequent non-IPD PS.	Infections account for a major cause of mortality in MSA [20]. Impaired detrusor contractility with post-void residual (PVR) > 150 mL seems to be the urodynamic finding distinguishing MSA from IPD [21-23].
Brain tumours	26.8/100,000/yr in adults (> 19 yrs), (17.9 benign, 8.9 malignant) [24].	Incontinence occurs mainly in frontal location (part of frontal syndrome or isolated in frontal location) [25].
Cerebral palsy	Cerebral palsy: 3.1-3.6/1,000 in children aged 8 yrs [26].	46% of patients with cerebral palsy suffer from UI, with 85% of patients having abnormal urodynamic studies (NDO most common 59%). Upper tract deterioration is rare (2.5%) [27].
Traumatic brain injury	235/100,000/yr [28].	44% storage dysfunction, 38% voiding dysfunction, 60% urodynamic abnormalities [29].
Normal pressure hydrocephalus	0.5% of the population > 60, up to 2.9% of those > 65 [30].	Classic triad of gait and cognitive disturbance along with UI. Incontinence affects 98-100% of patients [30].

Lesions and diseases between caudal brainstem and sacral spinal cord		
Spinal cord injury (SCI)	Prevalence of traumatic SCI in developed countries ranges from 280 to 906/million [31].	Neurogenic detrusor overactivity (NDO) and detrusor sphincter dyssynergia (DSD) (up to 95%) and detrusor underactivity (up to 83%) depending on the level of the lesion [32].
Spina bifida (SB)	Spina bifida 3-4/10,000 Lumbar and lumbosacral form are the most common (60%) [33].	Bladder function is impaired in up to 96% of SB patients [34]. Over 50% of patients are incontinent [35]. Patients with open and closed defects can have equally as severe neurogenic lower urinary tract dysfunction [36].
Lesions and diseases of the peripheral nervous system		
Lumbar spine Degenerative disease Disk prolapse Lumbar canal stenosis	Male (5%) and female (3%) > 35 yr have had a lumbosciatic episode related to disc prolapse. Incidence: approx. 5/100,000/yr More common in females > 45 yr.	26% difficulty to void and acontractile detrusor [37]. Detrusor underactivity (up to 83%) [32]. Tarlov cysts: early sensation of filling (70%), NDO (33%), urethral instability (33%) and stress urinary incontinence (SUI) (33%) [38].
Iatrogenic pelvic nerve lesions	Rectal cancer. Cervical cancer (multimodal therapy, radiotherapy and surgery). Endometriosis surgery.	After abdomino-perineal resection: 50% urinary retention. After total mesorectal excision: 10-30% voiding dysfunction [39].
Peripheral neuropathy Diabetes Other causes of peripheral neuropathy causing neuro-urological symptoms: alcohol abuse; lumbosacral zona and genital herpes; Guillain Barré syndrome.	Worldwide, prevalence of pharmacologically treated diabetes 8.3% [40].	Urgency/frequency +/- incontinence [41]. Hyposensitive and detrusor underactivity at later phase [41].
Disseminated central diseases		
Multiple sclerosis (MS)	Prevalence: 83/100,000 in Europe [42].	10% of MS patients present with voiding dysfunction at disease onset, 75% of patients will develop it after 10 yrs of MS [43]. DO: 86% [43]. DSD: 35% [43]. Detrusor underactivity: 25% [43].

3.2 Classification systems

3.2.1 Introduction

Relevant definitions can be found in the general ICS standardisation reports [2, 3, 44]. Supplementary online Tables S1 and S2 list the definitions from these references, partly adapted, and other definitions considered useful for clinical practice: https://uroweb.org/guideline/neuro-urology/?type=appendices-publications.

3.3 Diagnostic evaluation

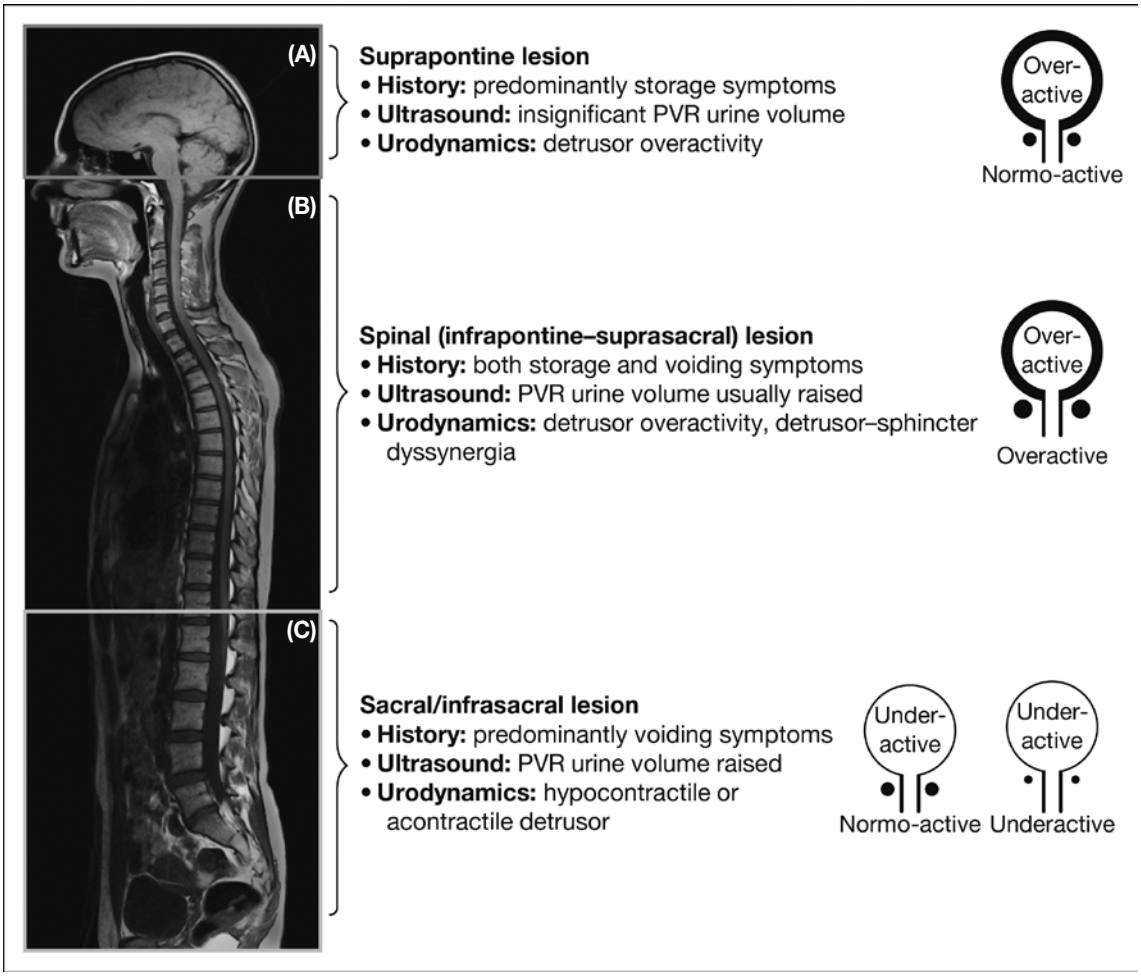
3.3.1 Introduction

The normal physiological function of the LUT depends on an intricate interplay between the sensory and motor nervous systems. When diagnosing neuro-urological symptoms, the aim is to describe the type of dysfunction involved. A thorough medical history, physical examination and bladder diary are mandatory before any additional diagnostic investigations can be planned. Results of the initial evaluation are used to decide the patient's long-term treatment and follow-up.

*3.3.2 **Classification systems***

The pattern of LUT dysfunction following neurological disease is determined by the site and nature of the lesion. A very simple classification system for use in daily clinical practice to decide on the appropriate therapeutic approach is provided in Figure 1 [6].

Figure 1: Patterns of lower urinary tract dysfunction following neurological disease



The pattern of LUT dysfunction following neurological disease is determined by the site and nature of the lesion. Panel (A) denotes the region above the pons, panel (B) the region between the pons and the sacral cord and panel (C) the sacral cord and infrasacral region. Figures on the right show the expected dysfunctional states of the detrusor-sphincter system. Figure adapted from Panicker et al. [6] with permission from Elsevier.
PVR = post-void residual.

*3.3.3 **Timing of diagnosis and treatment***

Early diagnosis and treatment are essential in both congenital and acquired neuro-urological disorders [45]. This helps to prevent irreversible changes within the LUT, even in the presence of normal reflexes [46, 47]. Furthermore, urological symptoms can be the presenting feature of neurological pathology [48, 49]. Early intervention can prevent irreversible deterioration of the LUT and UUT [50]. Long term follow up (life-long) is mandatory to assess risk of UUT damage, renal failure and bladder cancer [51-53].

*3.3.4 **Patient history***

History taking should include past and present symptoms and disorders (Table 4). It is the cornerstone of evaluation, as the answers will aid selection of diagnostic investigations and treatment options.

- In non-traumatic neuro-urological patients with an insidious onset, a detailed history may find that the condition started in childhood or adolescence [54].
- Urinary history consists of symptoms associated with both urine storage and voiding.
- Bowel history is important because patients with neuro-urological symptoms may also have related neurogenic bowel dysfunction [55].

- Sexual function may be impaired because of the neuro-urological condition [56].
- Special attention should be paid to possible warning signs and symptoms (e.g. pain, infection, haematuria and fever) requiring further investigation.
- Patients with SCI usually find it difficult to report urinary tract infection (UTI)-related symptoms accurately [57, 58].
- The presence of urinary, bowel and sexual symptoms without neurological symptoms could be suggestive of an underlying neurological disease or condition.
- Ambulatory status after acute SCI does not predict presence or absence of unfavourable urodynamic parameters [59].

Table 4: History taking in patients with suspected neuro-urological disorder

Past history
Childhood through to adolescence and into adulthood
Hereditary or familial risk factors
Specific female: menarche (age); this may suggest a metabolic disorder
Obstetric history
History of diabetes
Diseases, e.g. multiple sclerosis, parkinsonism, encephalitis, syphilis
Accidents and operations, especially those involving the spine and central nervous system
Present history
Present medication
Lifestyle (smoking, alcohol and drugs); may influence urinary, sexual and bowel function
Quality of life
Specific urinary history
Onset of urological history
Relief after voiding; to detect the extent of a neurological lesion in the absence of obstructive uropathy
Bladder sensation
Initiation of micturition (normal, precipitate, reflex, strain, Credé)
Interruption of micturition (normal, paradoxical, passive)
Enuresis
Mode and type of voiding (catheterisation)
Frequency, voided volume, incontinence, urgency episodes
Sexual history
Genital or sexual dysfunction symptoms
Sensation in genital area
Specific male: erection, (lack of) orgasm, ejaculation
Specific female: dyspareunia, (lack of) orgasm
Bowel history
Frequency and faecal incontinence
Desire to defecate
Defecation pattern
Rectal sensation
Initiation of defecation (digitation)
Neurological history
Acquired or congenital neurological condition
Mental status and comprehension
Neurological symptoms (somatic and sensory), with onset, evolution and any treatment
Spasticity or autonomic dysreflexia (especially in lesions at or above level Th 6)
Mobility and hand function

3.3.4.1 Bladder diaries

Bladder diaries provide data on the number of voids, voided volume, pad weight and incontinence and urgency episodes [3, 60]. Although a 24-hour bladder diary (recording should be done for three consecutive days) is reliable in women with UI [61, 62], no research has been done on bladder diaries in neuro-urological patients. Nevertheless, bladder diaries are considered a valuable diagnostic tool.

*3.3.5 **Patient quality of life questionnaires***

An assessment of the patient's present and expected future quality of life (QoL) is important to evaluate the effect of any therapy. Quality of life is an essential aspect of the overall management of neuro-urological patients, for example when evaluating treatment related changes on a patient's QoL [63]. The type of bladder management has been shown to affect health-related QoL (HRQoL) in patients with SCI [64, 65] and MS [66], as does the presence or absence of urinary and faecal incontinence [67]. Other research has also highlighted the importance of urological treatment and its impact on the urodynamic functionality of the neuro-urological patient in determining patient QoL [68].

In recent years a proliferation in the number of questionnaires to evaluate symptoms and QoL has been seen. Condition-specific questionnaires can be used to assess symptom severity and the impact of symptoms on QoL. A patient's overall QoL can be assessed using generic questionnaires. It is important that the questionnaire of choice has been validated in the neuro-urological population, and that it is available in the language that it is to be used in.

3.3.5.1 Available Questionnaires

Three condition-specific questionnaires for urinary or bowel dysfunction and QoL have been developed specifically for adult neuro-urological patients [69]. In MS and SCI patients the Qualiveen [70, 71] is validated and can be used for urinary symptoms. A short form of the Qualiveen is available [70, 71] and it has been translated into various languages [72-77]. Although several objective and subjective tools have been used to assess the influence of neurogenic bladder on QoL in SCI, the Quality life index-SCI and Qualiveen are the only validated condition-specific outcomes that have shown consistent sensitivity to neurogenic bladder [78]. The Neurogenic Bladder Symptom Score (NBSS) has been validated in neurological patients to measure urinary symptoms and their consequences [79, 80]. The QoL scoring tool related to Bowel Management (QoL-BM) [81] can be used to assess bowel dysfunction in MS and SCI patients.

In addition, sixteen validated questionnaires that evaluate QoL and asses urinary symptoms as a subscale or question in neuro-urological patients have been identified [82, 83] (Table 5). The condition-specific Incontinence-Quality of Life (I-QoL) questionnaire which was initially developed for the non-neurological population has now also been validated for neuro-urological patients [84].

A patient's overall QoL can be assessed by generic HRQoL questionnaires, the most commonly used being the I-QOL, King's Health Questionnaire (KHQ), or the Short Form 36-item and 12-item Health Survey Questionnaires (SF-36, SF-12) [69]. In addition, the quality-adjusted life year (QALY), quantifies outcomes, by weighing years of life spent in a specified health state, adjusted by a factor representing the value placed by society or patients on their specific health state [85].

No evidence was found for which validated questionnaires are the most appropriate for use, since no quality criteria for validated questionnaires have been assessed [69].

Table 5: Patient questionnaires

Questionnaire	Underlying neurological disorder	Bladder	Bowel	Sexual function
FAMS [86]	MS	X		X
FILMS [87]	MS	X	X	
HAQUAMS [88]	MS	X	X	X
I-QOL [84]	MS, SCI	X		X
MDS [89]	MS	X	X	
MSISQ-15 / MSISQ-19 [90, 91]	MS	X	X	X
MSQLI [92]	MS	X	X	X
MSQoL-54 [93]	MS	X	X	X
MSWDQ [94]	MS	X	X	
NBSS [95]	MS, SCI, Congenital neurogenic bladder	X		
QoL-BM [81]	SCI		X	
Qualiveen/SF-Qualiveen [71, 96]	MS, SCI	X		X
RAYS [97]	MS	X		X
RHSCIR [98]	SCI	X	X	X
Fransceschini [97]	SCI	X	X	X

3.3.6 ***Physical examination***

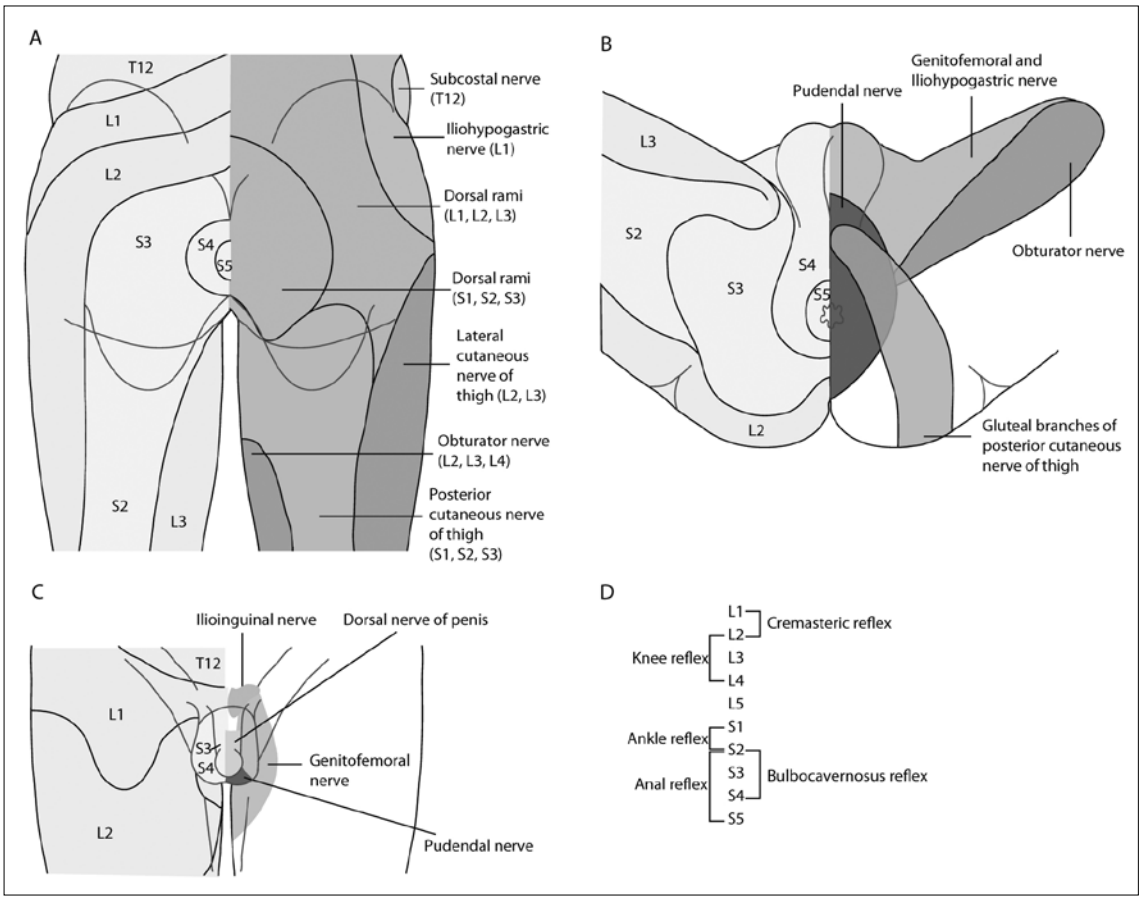
In addition to a detailed patient history, attention should be paid to possible physical and intellectual disabilities with respect to the planned investigations [99, 100]. Neuro-urological status should be described as completely as possible (Figure 2) [6]. Patients with a high spinal cord lesion or supraspinal neurological lesions may suffer from a significant drop in blood pressure when moved into a sitting or standing position. All sensations and reflexes in the urogenital area must be tested [6]. Furthermore, detailed testing of the anal sphincter and pelvic floor functions must be performed (Figure 2) [6, 101]. It is essential to have this clinical information to reliably interpret later diagnostic investigations.

Additionally, urinalysis, blood chemistry, ultrasonography, residual and free flowmetry and incontinence quantification should be performed as part of the routine assessment of neuro-urological patients [6, 102].

3.3.6.1 Autonomic dysreflexia

Autonomic dysreflexia (AD) is a sudden and exaggerated autonomic response to various stimuli in patients with SCI or spinal dysfunction. It generally manifests at or above level Th 6. The stimulus can be distended bladder or bowel. For example, iatrogenic stimuli during cystoscopy or urodynamics can trigger AD [103]. It can also be secondary to sexual stimulation or a noxious stimulus, e.g. infected toe nail or pressure sore. Autonomic dysreflexia is defined by an increase in systolic blood pressure > 20 mmHg from baseline [104] and can have life-threatening consequences if not properly managed.

Figure 2: Lumbosacral dermatomes, cutaneous nerves, and reflexes



The physical examination includes testing sensations and reflexes mediated through the lower spinal cord. Abnormal findings would suggest a lesion affecting the lumbosacral segments; mapping out distinct areas of sensory impairment helps to further localise the site of the lesion. Distribution of dermatomes (areas of skin mainly supplied by a single spinal nerve) and cutaneous nerves over the perianal region and back of the upper thigh (A), the perineum [105] (B), male external genitalia [106] (C) and root values of lower spinal cord reflexes (D). Figure adapted from Panicker et al. [6] with parts A-C adapted from Standring [107], both with permission from Elsevier.

Table 6: Neurological items to be specified

Sensation S2-S5 (both sides)
Presence (increased/normal/reduced/absent)
Type (light touch/pin prick)
Affected dermatomes
Reflexes (increased/normal/reduced/absent)
Bulbocavernous reflex
Perianal/anal reflex
Knee and ankle reflexes
Plantar responses (Babinski)
Anal sphincter tone
Presence (increased/normal/reduced/absent)
Voluntary contractions of anal sphincter and pelvic muscles (increased/normal/reduced/absent)
Prostate palpation
Descensus (prolapse) of pelvic organs

3.3.6.2 Summary of evidence and recommendations for history taking and physical examination

Summary of evidence	**LE**
Early diagnosis and treatment are essential in both congenital and acquired neuro-urological disorders to prevent irreversible changes within the LUT.	4
An extensive general history is the basis of evaluation focusing on past and present symptoms including urinary, sexual, bowel and neurological functions.	4
Assessment of present and expected future QoL is an essential aspect of the overall management of neuro-urological patients and is important to evaluate the effect of any therapy.	2a
Quality of life assessment should be completed with validated QoL questionnaires for neuro-urological patients.	1a
Bladder diaries provide data on the number of voids, voided volume, pad weight and incontinence and urgency episodes.	3

Recommendations	**Strength rating**
History taking	
Take an extensive general history, concentrating on past and present symptoms.	Strong
Take a specific history for each of the four mentioned functions - urinary, bowel, sexual and neurological.	Strong
Pay special attention to the possible existence of alarm signs (e.g. pain, infection, haematuria, fever) that warrant further specific diagnosis.	Strong
Assess quality of life when evaluating and treating the neuro-urological patient.	Strong
Use available validated tools including the Qualiveen and I-QoL for urinary symptoms and the QoL-BM for bowel dysfunction in multiple sclerosis and spinal cord injury patients. In addition, generic (SF-36 or KHQ) questionnaires can be used.	Strong
Use MSISQ-15 and MSISQ-19 to evaluate sexual function in multiple sclerosis patients.	Strong
Physical examination	
Acknowledge individual patient disabilities when planning further investigations.	Strong
Describe the neurological status as completely as possible, sensations and reflexes in the urogenital area must all be tested.	Strong
Test the anal sphincter and pelvic floor functions.	Strong
Perform urinalysis, blood chemistry, bladder diary, residual and free flowmetry, incontinence quantification and urinary tract imaging.	Strong

I-QoL = Incontinence Quality of Life Instrument; QoL-BM = Quality of Life Bowel Management scoring tool; KHQ = King's Health Questionnaire; SF-36 = Short Form 36-item Health Survey Questionnaires; MSISQ 15/19 = Multiple Sclerosis Intimacy and Sexuality Questionnaire 15/19 question version.

3.3.7 ***Urodynamics***

3.3.7.1 Introduction

Urodynamic investigation is the only method that can objectively assess the function and dysfunction of the LUT. In neuro-urological patients, invasive urodynamic investigation is even more challenging than in general patients. Any technical source of artefacts must be critically considered. It is essential to maintain the quality of the urodynamic recording and its interpretation [1]. Same session repeat urodynamic investigations are crucial in clinical decision making, since repeat measurements may yield completely different results [108].

In patients at risk of AD, it is advisable to measure blood pressure during the urodynamic study [109, 110]. The rectal ampulla should be empty of stool before the start of the investigation. All urodynamic findings must be reported in detail and performed, according to the ICS technical recommendations and standards [1, 111].

3.3.7.2 Urodynamic tests

Free uroflowmetry and assessment of residual urine: Provides a first impression of the voiding function and is compulsory prior to planning any invasive urodynamics in patients able to void. For reliable information, it should be repeated at least two to three times [1]. Possible pathological findings include a low flow rate, low voided volume, intermittent flow, hesitancy and residual urine. Care must be taken when assessing the results in patients unable to void in a normal position, as both flow pattern and rate may be modified by inappropriate positions.

Filling cystometry: This test is the only method for quantifying the patient's filling function. The status of LUT function must be documented during the filling phase. However, this technique has limited use as a solitary procedure. It is much more effective combined with bladder pressure measurement during micturition and is even more effective in video-urodynamics.

The bladder should be empty at the start of filling. A physiological filling rate should be used with body-warm saline. Possible pathological findings include DO, low bladder compliance, abnormal bladder sensations, incontinence, and an incompetent or relaxing urethra. There is some evidence that a bladder capacity < 200 mL and detrusor pressures over 75 cm H_2O are independent risk factors for UUT damage in patients with SCI [51].

Detrusor leak point pressure [112]: Appears to have no use as a diagnostic tool. Some positive findings have been reported [113-115], but sensitivity is too low to estimate the risk to the UUT or for secondary bladder damage [116, 117].

Pressure flow study: Reflects the coordination between detrusor and urethra or pelvic floor during the voiding phase. It is even more effective if combined with filling cystometry and video-urodynamics. Lower urinary tract function must be recorded during the voiding phase. Possible pathological findings include detrusor underactivity, bladder outlet obstruction (BOO), DSD, a high urethral resistance, and residual urine.

Most types of obstruction caused by neuro-urological disorders are due to DSD [118, 119], non-relaxing urethra, or non-relaxing bladder neck [120, 121]. Pressure-flow analysis mainly assesses the amount of mechanical obstruction caused by the urethra's inherent mechanical and anatomical properties and has limited value in patients with neuro-urological disorders.

Electromyography (EMG): Reflects the activity of the external urethral sphincter, the peri-urethral striated musculature, the anal sphincter and the striated pelvic floor muscles. Correct interpretation may be difficult due to artefacts introduced by other equipment. In the urodynamic setting, an EMG is useful as a gross indication of the patient's ability to control the pelvic floor. Possible pathological findings include inadequate recruitment upon specific stimuli (e.g. bladder filling, involuntary detrusor contractions, onset of voiding, coughing, Valsalva manoeuvre) suggesting a diagnosis of DSD [122].

Urethral pressure measurement: Has a very limited role in neuro-urological disorders. There is no consensus on parameters indicating pathological findings [123].

Video-urodynamics: Is the combination of filling cystometry and pressure flow studies with imaging. It is the optimum procedure for urodynamic investigation in neuro-urological disorders [5]. Possible pathological findings include all those described in the cystometry and the pressure flow study sections, and any morphological pathology of the LUT and reflux to the UUT [124].

Ambulatory urodynamics: This is the functional investigation of the urinary tract, which predominantly uses the natural filling of the urinary tract to reproduce the patient's normal activity. Although this type of study might be

considered when conventional urodynamics does not reproduce the patient's symptoms, its role in the neuro-urological patient still needs to be determined [125, 126].

Triggered tests during urodynamics: Lower urinary tract function can be provoked by coughing, triggered voiding, or anal stretch. Fast-filling cystometry with cooled saline (the 'ice water test') will discriminate between upper and lower motor neuron lesions [127, 128]. Patients with upper motor neuron lesions develop a detrusor contraction if the detrusor is intact, while patients with lower motor neuron lesions do not. However, the test does not seem to be fully discriminative in other types of patients [129].

Previously, a positive bethanechol test [130] (detrusor contraction > 25 cm H_2O) was thought to indicate detrusor denervation hypersensitivity and the muscular integrity of an acontractile detrusor. However, in practice, the test has given equivocal results. A variation of this method was reported using intravesical electromotive administration of the bethanechol [131], but there was no published follow-up. Currently, there is no indication for this test.

3.3.7.3 Specialist uro-neurophysiological tests

The following tests are advised as part of the neurological work-up [132]:

- electromyography (in a neurophysiological setting) of pelvic floor muscles, urethral sphincter and/or anal sphincter;
- nerve conduction studies of pudendal nerve;
- reflex latency measurements of bulbocavernosus and anal reflex arcs;
- evoked responses from clitoris or glans penis;
- sensory testing on bladder and urethra.

Other elective tests, for specific conditions, may become obvious during the work-up and urodynamic investigations.

3.3.7.4 Summary of evidence and recommendations for urodynamics and uro-neurophysiology

Summary of evidence	**LE**
Urodynamic investigation is the only method that can objectively assess the (dys-)function of the LUT.	2a
Video-urodynamics is the optimum procedure for urodynamic investigation in neuro-urological disorders.	4
Specific uro-neurophysiological tests are elective procedures and should only be carried out in specialised settings.	4

Recommendations	**Strength rating**
Perform a urodynamic investigation to detect and specify lower urinary tract (dys-)function, use same session repeat measurement as it is crucial in clinical decision making.	Strong
Non-invasive testing is mandatory before invasive urodynamics is planned.	Strong
Use video-urodynamics for invasive urodynamics in neuro-urological patients. If this is not available, then perform a filling cystometry continuing into a pressure flow study.	Strong
Use a physiological filling rate and body-warm saline.	Strong

3.3.8 ***Renal function***

In many patients with neuro-urological disorders, the UUT is at risk, particularly in patients who develop high detrusor pressure during the filling phase. Although effective treatment can reduce this risk, there is still a relatively high incidence of renal morbidity [133, 134]. Patients with SCI or SB have a higher risk of developing renal failure compared with patients with slowly progressive non-traumatic neurological disorders, such as MS and Parkinson's disease (PD) [135].

Caregivers must be informed of this risk and instructed to watch carefully for any signs or symptoms of a possible deterioration in the patient's renal function. In patients with poor muscle mass cystatin C based glomerular filtration rate (GFR) is more accurate in detecting chronic kidney disease than serum creatinine estimated GFR [136, 137]. There are no high level evidence publications available which show the optimal management to preserve renal function in these patients [138].

3.4 Disease management

*3.4.1 **Introduction***

The primary aims for treatment of neuro-urological symptoms, and their priorities, are [139, 140]:

- protection of the UUT;
- achievement (or maintenance) of urinary continence;
- restoration of LUT function;
- improvement of the patient's QoL.

Further considerations are the patient's disability, cost-effectiveness, technical complexity and possible complications [140].

Renal failure is the main mortality factor in SCI patients who survive the trauma [141, 142]. Keeping the detrusor pressure during both the filling and voiding phases within safe limits significantly reduces the mortality from urological causes in these patients [143-145] and has consequently become the top priority in the treatment of patients with neuro-urological symptoms [139, 140].

In patients with high detrusor pressure during the filling phase (DO, low bladder compliance), treatment is aimed primarily at conversion of an overactive, high-pressure bladder into a low-pressure reservoir despite the resulting residual urine [139]. Reduction of the detrusor pressure contributes to urinary continence, and consequently to social rehabilitation and QoL. It is also pivotal in preventing UTIs [146, 147]. However, complete continence cannot always be obtained.

*3.4.2 **Non-invasive conservative treatment***

3.4.2.1 Assisted bladder emptying - Credé manoeuvre, Valsalva manoeuvre, triggered reflex voiding

Incomplete bladder emptying is a serious risk factor for UTI, high intravesical pressure and incontinence. Methods to improve the voiding process should therefore be practiced.

Bladder expression: The downwards movement of the lower abdomen by suprapubic compression (Credé) or by abdominal straining (Valsalva) leads to an increase in intravesical pressure, and generally also causes a reflex sphincter contraction [148, 149]. The latter may increase bladder outlet resistance and lead to inefficient emptying. The high pressures created during these procedures are hazardous for the urinary tract [150, 151]. Therefore, their use should be discouraged unless urodynamics show that the intravesical pressure remains within safe limits [140].

Long-term complications are unavoidable for both methods of bladder emptying [149]. The already weak pelvic floor function may be further impaired, thus introducing or exacerbating already existing stress urinary incontinence [151].

Triggered reflex voiding: Stimulation of the sacral or lumbar dermatomes in patients with a upper motor neuron lesion can elicit a reflex detrusor contraction [151]. The risk of high pressure voiding is present and interventions to decrease outlet resistance may be necessary [152]. Triggering can induce AD, especially in patients with high level SCI (at or above Th 6) [153]. All assisted bladder emptying techniques require low outlet resistance. Even then, high detrusor pressures may still be present. Hence, patients need dedicated education and close urodynamic and urological surveillance [151, 154, 155].

Note: In the literature, including some of the references cited here, the concept "reflex voiding" is sometimes used to cover all three assisted voiding techniques described in this section.

External appliances: Social continence may be achieved by collecting urine during incontinence, for instance using pads. Condom catheters with urine collection devices are a practical method for men [140]. The penile clamp is absolutely contraindicated in case of NDO or low bladder compliance because of the risk of developing high intravesical pressure and pressure sores/necrosis in cases of altered/absent sensations.

3.4.2.2 Neuro-urological rehabilitation

3.4.2.2.1 Bladder rehabilitation including electrical stimulation

The term bladder rehabilitation summarises treatment options that aim to re-establish bladder function in patients with neuro-urological symptoms. Strong contraction of the urethral sphincter and/or pelvic floor, as well as anal dilatation, manipulation of the genital region, and physical activity inhibit micturition in a reflex manner [140, 156]. The first mechanism is affected by activation of efferent nerve fibres, and the latter ones are produced by activation of afferent fibres [116]. Electrical stimulation of the pudendal nerve afferents strongly inhibits the micturition reflex and detrusor contraction [157]. This stimulation might then support the restoration of the balance between excitatory and inhibitory inputs at the spinal or supraspinal level [140, 158]. Evidence

for bladder rehabilitation using electrical stimulation in neurological patients is mainly based on small non-comparative studies with high risk of bias.

Peripheral temporary electrostimulation: Tibial nerve stimulation and transcutaneous electrical nerve stimulation (TENS) might be effective and safe for treating neurogenic LUT dysfunction, but more reliable evidence from well-designed randomised controlled trials (RCTs) is required to reach definitive conclusions [158-160]. In post-stroke patients TENS has been shown to effectively improve urodynamic findings and QoL [161-163].

Peripheral temporary electrostimulation combined with pelvic floor muscle training and biofeedback: In MS patients, combining active neuromuscular electrical stimulation with pelvic floor muscle training and EMG biofeedback can achieve a substantial reduction of neuro-urological symptoms [164, 165]. This treatment combination seems to be more effective than either therapy alone [166, 167]. However, the combination of intravaginal electrostimulation and pelvic floor muscle training was not superior to pelvic floor muscle training alone in reducing urinary incontinence in women with incomplete spinal cord injury [168].

Intravesical electrostimulation: Intravesical electrostimulation can increase bladder capacity and improve bladder filling sensation in patients with incomplete SCI or myelomeningocele (MMC) [169]. In patients with neurogenic detrusor underactivity, intravesical electrostimulation may also improve voiding and reduce residual volume [170, 171].

Repetitive transcranial magnetic stimulation: Although improvement of neuro-urological symptoms has been described in PD and MS patients, this technique is still under investigation [172, 173].

Summary: To date, bladder rehabilitation techniques are mainly based on electrical or magnetic stimulation; however, there is a lack of well-designed studies.

3.4.2.3 Drug treatment

A single, optimal, medical therapy for neuro-urological symptoms is not always available. Commonly, a combination of different therapies (e.g. intermittent catheterisation and antimuscarinic drugs) is advised to prevent urinary tract damage and improve long-term outcomes, particularly in patients with a suprasacral SCI or MS [151, 174-176].

3.4.2.3.1 Drugs for storage symptoms

Antimuscarinic drugs: Are the first-line choice for treating NDO, increasing bladder capacity and reducing episodes of UI secondary to NDO by the inhibition of parasympathetic pathways [140, 177-183]. Antimuscarinic drugs have been used for many years to treat patients with NDO [181, 182, 184], and the responses of individual patients to antimuscarinic treatment are variable. Despite a meta-analysis confirming the clinical and urodynamic efficacy of antimuscarinic therapy compared to placebo in adult NDO, a more recent integrative review has indicated that the information provided is still too limited for clinicians to be able to match trial data to the needs of individual patients with SCI, mainly due to the lack of use of standardised clinical evaluation tools such as the American Spinal Injury Association bladder diary and validated symptoms score [182, 185].

Higher doses or a combination of antimuscarinic agents may be an option to maximise outcomes in neurological patients [178, 179, 186-189]. However, these drugs have a high incidence of adverse events, which may lead to early discontinuation of therapy. Despite this, NDO patients have generally shown better treatment adherence compared to idiopathic DO patients [190].

Choice of antimuscarinic agent: Oxybutynin [140, 178, 179, 181, 182, 191], trospium [182, 188, 192], tolterodine [193] and propiverine [182, 194] are established, effective and well tolerated treatments even in long-term use [181, 182, 195, 196]. Darifenacin [197, 198] and solifenacin [199] have been evaluated in NDO secondary to SCI and MS [182, 197-199] with results similar to other antimuscarinic drugs. A pilot study using solifenacin in NDO due to PD showed an improvement in UI [200]. Fesoterodine, an active metabolite of tolterodine, has also been introduced; to date there has been no published clinical evidence for its use in the treatment of neuro-urological disorders. Favourable results with the new drug imidafenacin have been reported in suprapontine as well as SCI patients [201, 202].

Side effects: Controlled-release antimuscarinics have some minor side effects, e.g. dry mouth [203]. It has been suggested that different ways of administration may help to reduce side effects [204]. Imidafenacine has been safely used in neurological patients with no worsening of cognitive function [201].

Beta-3-adrenergic receptor agonists
The role of mirabegron in neuro-urological patients is still unclear. In MS and SCI patients, with very short follow up, mirabegron has not demonstrated any significant effect on detrusor pressure or cystometric capacity despite the reported improvement in LUTS [205, 206]. A significant subjective improvement in OAB symptoms has also been reported using lower dosages of mirabegron in patients affected by CNS lesions without any negative effects on voiding function [207]. A standard dosage of 50 mg has been found effective with no worsening of cognitive function in patients with PD [208]. Combination therapy with mirabegron and desmopressin in MS patients has shown promising results; however, clinical experience is still very limited in neuro-urological populations [209].

Other drugs
In preliminary studies, improvements in daily incontinence rates, nocturia, daytime and 24 hour voids, as well as the low risk of adverse events, suggest that cannabinoids may be effective and safe in MS patients [210]. A concomitant improvement in OAB symptoms has been reported in male MS patients using daily tadalafil to treat neurogenic erectile dysfunction (ED) [211]. A systematic review found that desmopressin may be effective for treating nocturia in MS patients; however, adverse events were common, with the included studies being heterogeneous and of low quality [212].

3.4.2.3.2 Drugs for voiding symptoms
Detrusor underactivity: Cholinergic drugs, such as bethanechol and distigmine, have been considered to enhance detrusor contractility and promote bladder emptying, but are not frequently used in clinical practice [213]. Only preclinical studies have documented the potential benefits of cannabinoid agonists for improving detrusor contractility when administered intravesically [214, 215].

Decreasing bladder outlet resistance: α-blockers (e.g. tamsulosin, naftopidil and silodosin) seem to be effective for decreasing bladder outlet resistance, PVR and AD [216-218].

Increasing bladder outlet resistance: Several drugs have shown efficacy in selected cases of mild SUI, but there are no high-level evidence studies in neurological patients [140].

3.4.2.4 Summary of evidence and recommendations for drug treatments

Summary of evidence	**LE**
Long-term efficacy and safety of antimuscarinic therapy for NDO is well documented.	1a
Mirabegron does not improve urodynamic outcomes in NDO patients.	1b
Maximise outcomes for neurogenic detrusor overactivity by considering a combination therapy.	3

Recommendations	**Strength rating**
Use antimuscarinic therapy as the first-line medical treatment for neurogenic detrusor overactivity.	Strong
Prescribe α-blockers to decrease bladder outlet resistance.	Strong
Do not prescribe parasympathomimetics for underactive detrusor.	Strong

3.4.2.5 Minimally invasive treatment
3.4.2.5.1 Catheterisation
Intermittent self- or third-party catheterisation [219, 220] is the preferred management for neuro-urological patients who cannot effectively empty their bladders [140]. Sterile IC, as originally proposed by Guttmann and Frankel [219], significantly reduces the risk of UTI and bacteriuria [140, 221, 222], compared with clean IC introduced by Lapides *et al.* [220]. However, it has not yet been established whether or not the incidence of UTI, other complications and user satisfaction are affected by either sterile or clean IC, coated or uncoated catheters or by any other strategy [223].

Sterile IC cannot be considered a routine procedure [140, 222]. Aseptic IC is an alternative to sterile IC [224]. The use of hydrophilic catheters was associated with a lower rate of UTI [225].

Contributing factors to contamination are insufficient patient education and the inherently greater risk of UTI in neuro-urological patients [140, 226-230]. The average frequency of catheterisations per day is four to six times [231] and the catheter size most often used is between 12-16 Fr. In aseptic IC, an optimum frequency of five

times showed a reduction of UTI [231]. Ideally, bladder volume at catheterisation should, as a rule, not exceed 400-500 mL.

Indwelling transurethral catheterisation and, to a lesser extent, suprapubic cystostomy are associated with a range of complications as well as an enhanced risk for UTI [140, 232-239]; therefore, both procedures should be avoided, when possible. Silicone catheters are preferred as they are less susceptible to encrustation and because of the high incidence of latex allergy in the neuro-urological patient population [240].

3.4.2.5.2 Summary of evidence and recommendations for catheterisation

Summary of evidence	LE
Intermittent catheterisation is the standard treatment for patients who are unable to empty their bladder.	3
Indwelling transurethral catheterisation and suprapubic cystostomy are associated with a range of complications as well as an enhanced risk for UTI.	3

Recommendations	Strength rating
Use intermittent catheterisation, whenever possible aseptic technique, as a standard treatment for patients who are unable to empty their bladder.	Strong
Thoroughly instruct patients in the technique and risks of intermittent catheterisation.	Strong
Avoid indwelling transurethral and suprapubic catheterisation whenever possible.	Strong

3.4.2.5.3 Intravesical drug treatment

To reduce DO, antimuscarinics can also be administered intravesically [204, 241-244]. The efficacy, safety and tolerability of intravesical administration of 0.1% oxybutynin hydrochloride compared to its oral administration for treatment of NDO has been demonstrated in a recent randomised controlled study [204]. This approach may reduce adverse effects due to the fact that the antimuscarinic drug is metabolised differently [241] and a greater amount is sequestered in the bladder, even more than with electromotive administration [242].

The vanilloids, capsaicin and resiniferatoxin, desensitise the C-fibres for a period of a few months [245, 246]. Clinical studies have shown that resiniferatoxin has limited clinical efficacy compared to botulinum toxin A injections in the detrusor [245].

Although preliminary data suggest that intravesical vanilloids might be effective for treating neurogenic LUT dysfunction, their safety profile appears to be unfavourable [247]. Currently, there is no indication for the use of these substances, which are not licensed for intravesical treatment.

3.4.2.5.4 Summary of evidence and recommendations for intravesical drug treatment

Summary of evidence	LE
A significant reduction in adverse events was observed for intravesical administration of oxybutynine compared to oral administration.	1a

Recommendation	Strength rating
Offer intravesical oxybutynin to neurogenic detrusor overactivity patients with poor tolerance to the oral route.	Strong

3.4.2.5.5 Botulinum toxin injections in the bladder

Botulinum toxin A causes a long-lasting but reversible chemical denervation that lasts for about nine months [248, 249]. The toxin injections are mapped over the detrusor in a dosage that depends on the preparation used. Botulinum toxin A has been proven effective in patients with neuro-urological disorders due to MS, SCI and PD in multiple RCTs and meta-analyses [250-252]. Urodynamic studies might be necessary after treatment in patients with maximal filling pressure of > 40 cm H_2O cm in order to monitor the effect of the injections on bladder pressure [253]. Repeated injections seem to be possible without loss of efficacy, even after initial low response rates, based on years of follow up [248, 254-257]. The clinical efficacy of botulinum toxin A injection in patients with low morbidity after failure of augmentation enterocystoplasty has been demonstrated [258]. A switch between different toxin variations may improve responsiveness [259]. The most frequent side

effects are UTIs, urinary retention and haematuria [260]. Intermittent catheterisation may become necessary, this is especially relevant in MS patients as they do not often perform IC prior to intravesical botulinum toxin injections. However, a lower dose of botulinum toxin A (100 U) may reduce the rate of clean IC in MS patients [261]. Rare complications include generalised muscle weakness and AD [260]. Current research focuses on different delivery approaches to injection such as liposome encapsulated botulinum toxin to decrease side effects [262]. Neuro-urological patients with an indwelling catheter and concomitant bladder pain and/or catheter bypass leakage could benefit from intravesical botulinum injections [263].

3.4.2.5.6 Bladder neck and urethral procedures

Reduction of the bladder outlet resistance may be necessary to protect the UUT. This can be achieved by chemical denervation of the sphincter or by surgical interventions (bladder neck or sphincter incision or urethral stent – Section 3.4.3.1). Incontinence may result and can be managed by external devices (Section 3.4.2.1).

Botulinum toxin A: This can be used to treat DSD effectively by injecting the sphincter at a dose that depends on the preparation used. The dyssynergia is abolished only for a few months, necessitating repeat injections. The efficacy of this treatment has been reported to be high with few adverse effects [264-266]. However, a recent Cochrane report concluded that, because of limited evidence, future RCTs assessing the effectiveness of botulinum toxin A injections also need to address the uncertainty about the optimal dose and mode of injection [267]. In addition, this therapy is not licensed.

Balloon dilatation: Favourable immediate results were reported [268], but there have been no further reports since 1994; therefore, this method is no longer recommended.

Increasing bladder outlet resistance: This can improve the continence condition. Despite early positive results with urethral bulking agents, a relative early loss of continence is reported in patients with neuro-urological disorders [140, 269, 270].

Urethral inserts: Urethral plugs or valves for the management of (female) stress incontinence have not been applied in neuro-urological patients. The experience with active pumping urethral prosthesis for treatment of the underactive or acontractile detrusor were disappointing [271].

3.4.2.5.7 Summary of evidence and recommendations for botulinum toxin A injections and bladder neck procedures

Summary of evidence	**LE**
Botulinum toxin A has been proven effective in patients with neuro-urological disorders due to MS or SCI in multiple RCTs and meta-analyses.	1a
Bladder neck incision is indicated only for secondary changes (fibrosis) at the bladder neck.	4

Recommendations	**Strength rating**
Use botulinum toxin injection in the detrusor to reduce neurogenic detrusor overactivity in multiple sclerosis or spinal cord injury patients if antimuscarinic therapy is ineffective.	Strong
Bladder neck incision is effective in a fibrotic bladder neck.	Strong

*3.4.3 **Surgical treatment***

There is considerable heterogeneity in outcome parameters and definitions of cure used to report on outcome of surgical interventions for SUI in neuro-urological patients [272]. The heterogeneity of outcome reporting makes it difficult to interpret and compare different studies and therapies. A consistent comparison of the outcomes of therapy can only be made after standardisation of outcome parameters and definitions of cure or success; therefore, it would seem prudent to develop a core outcome set (COS) for use in UI research in neuro-urological patients [272]. Until such a COS is developed it would seem feasible to use both a subjective and objective outcome parameter and the combination of both to define cure [272]. Due to the importance of QoL for neuro-urological patients a disease-specific QoL questionnaire or a bother questionnaire validated for neuro-urological patients should be used as the subjective outcome parameter [272].

3.4.3.1 Bladder neck and urethral procedures

Increasing the bladder outlet resistance has the inherent risk of causing high intravesical pressure. Procedures to treat sphincteric incontinence are therefore suitable only when the detrusor activity can be controlled and when no significant reflux is present. A simultaneous bladder augmentation and IC may be necessary [140].

Urethral sling: Various materials have been used for this procedure with enduring positive results. The procedure is established in women with the ability to self-catheterise [140, 273-276]. There is growing evidence that synthetic slings can be used effectively with acceptable medium to long-term results and minimal morbidity in neurological patients [277, 278]. Besides the pubovaginal sling, which has been considered the procedure of choice in this subgroup of patients, recent reports suggest that both the transobturator and the retropubic approaches may also be considered, with similar failure rates and a reduction in the need for IC. However, for both approaches a higher incidence of *de novo* urgency was reported [278, 279]. In men, both autologous and synthetic slings may also be an alternative [280-284].

Artificial urinary sphincter (AUS): This device was introduced by Light and Scott for patients with neuro-urological disorders [285]. It has stood the test of time and acceptable long-term outcomes can be obtained [286]. However, the complication rates and re-operation rates are higher than in non-neurogenic patient groups (up to 60%), so it is advisable that patients are conscientiously informed about the success rates as well as the complications that may occur after the procedure [287, 288]. In a case series with 25 years follow up only 7.1% of patients were revision free at 20 years [289]. Re-interventions are commonly due to infection, urethral atrophy or erosion and mechanical failure.

There is growing interest in the use of this device in women with development of laparoscopic and robot-assisted approaches which appear to reduce infection and erosion rates [290-293]. Long-term surgical and patient-reported outcomes are needed to determine the role of AUS placement in female patients with neurogenic SUI [294].

Adjustable continence device - ProACT/ACT®: The efficacy of this device has been reported mainly in post-prostatectomy incontinence. A marginally lower cure rate has been reported in neurological patients when compared to non-neurological patients [295]. A retrospective study in neuro-urological patients reported a low rate of efficacy and high complication rate for this device [296].

Functional sphincter augmentation: Transposing the gracilis muscle to the bladder neck [297] or proximal urethra [298], can enable the possible creation of a functional autologous sphincter by electrical stimulation [297-299]; therefore, raising the prospect of restoring control over the urethral closure.

Bladder neck and urethra reconstruction: The classical Young-Dees-Leadbetter procedure [300] for bladder neck reconstruction in children with bladder exstrophy, and Kropp urethra lengthening [301] improved by Salle [302], are established methods to restore continence provided that IC is practiced and/or bladder augmentation is performed [140, 303].

Endoscopic techniques for treating anatomic bladder outlet obstruction [304]:

- Transurethral resection of the prostate is indicated in male patients with refractory LUT symptoms due to benign prostatic obstruction. Special consideration should be given to pre-operative abnormal sphincter function which can lead to *de novo* or persistent UI [305, 306].
- Bladder neck resection is indicated in patients with high PVR and when a prominent obstruction of the sclerotic ring in the bladder neck is identified during cystoscopy. The resection can be performed between the three or nine o'clock position or full circle [307].
- Urethrotomy is indicated in patients with urethral strictures. Cold knife or neodymium:YAG contact laser urethrotomy at the twelve o'clock position can be performed [308, 309]. In recurrent strictures, open surgery should be considered.
- Sphincterotomy has been shown to be an efficient technique for the resolution of AD, hydronephrosis and recurrent UTI, and for decreasing detrusor pressures, PVR and vesicoureteral reflux. It is irreversible and should be limited to men who are able to wear a condom catheter. By staged incision, bladder outlet resistance can be reduced without completely losing the closure function of the urethra [139, 140, 310]. The incision with less complications is the twelve o'clock sphincterotomy with cold knife [311] or neodymium:YAG laser [312]. Sphincterotomy needs to be repeated at regular intervals in many patients [313], but it is efficient and does not cause severe adverse effects [139, 268]. Secondary narrowing of the bladder neck may occur, for which combined bladder neck incision might be considered [314].

Bladder neck incision: This is indicated only for secondary changes at the bladder neck (fibrosis) [139, 315]. This procedure is not recommended in patients with detrusor hypertrophy, which causes thickening of the bladder neck [139].

Stents: Implantation of urethral stents results in continence being dependent on adequate closure of the bladder neck [140]. The results are comparable with sphincterotomy and the stenting procedure has a shorter duration of surgery and hospital stay [316, 317]. However, the costs [139], possible complications and re-interventions [318, 319] are limiting factors in their use [320-323].

3.4.3.2 Denervation, deafferentation, sacral neuromodulation

Sacral anterior root stimulation (SARS) is aimed at producing detrusor contraction. The technique was developed by Brindley [324] and is only applicable to complete lesions above the implant location, as its stimulation amplitude is over the pain threshold. The urethral sphincter efferents are also stimulated, but because the striated muscle relaxes faster than the smooth muscle of the detrusor, so-called "post-stimulus voiding" occurs. This approach has been successful in highly selected patients [325-327]. Although it has been shown that detrusor pressure during SARS decreases over time, the changes do not seem to be clinically relevant during the first decade after surgery [328]. By changing the stimulation parameters, this method can also induce defecation or erection. A recent study reported that Charcot spinal arthropathy should be considered as a potential long-term complication of SARS, leading to spinal instability and to SARS dysfunction [329].

Sacral rhizotomy, also known as sacral deafferentation, has achieved some success in reducing DO [330-332], but nowadays, it is used mostly as an adjuvant to SARS [325, 333-336]. Alternatives to rhizotomy are sought in this treatment combination [337-339].

Sacral neuromodulation [340] might be effective and safe for treating neuro-urological symptoms, but there is a lack of RCTs and it is unclear which neurological patients are most suitable [341-344].

3.4.3.3 Bladder covering by striated muscle

When the bladder is covered by striated muscle, that can be stimulated electrically, or ideally that can be contracted voluntarily, voiding function can be restored to an acontractile bladder. The rectus abdominis [345] and latissimus dorsi [346] have been used successfully in patients with neuro-urological symptoms [347, 348].

3.4.3.4 Bladder augmentation

The aim of auto-augmentation (detrusor myectomy) is to reduce DO or improve low bladder compliance. The advantages are: low surgical burden, low rate of long-term adverse effects, positive effect on patient QoL, and it does not preclude further interventions [139, 140, 349-352].

Replacing or expanding the bladder by intestine or other passive expandable coverage will improve bladder compliance and at least reduce the pressure effect of DO [353, 354]. Improved QoL and stable renal function has been reported during long-term follow-up [355]. Patients performing IC with augmentation cystoplasty had better urinary function and satisfaction with their urinary symptoms compared to patients performing IC with or without botulinum toxin treatment [356]. Long-term complications included bladder perforation (1.9%), mucus production (12.5%), metabolic abnormalities (3.35%), bowel dysfunction (15%), and stone formation (10%) [355].

The procedure should be used with caution in patients with neuro-urological symptoms, but may become necessary if all less-invasive treatment methods have failed. Special attention should be paid to patients with pre-operative renal scars since metabolic acidosis can develop [357]. Bladder substitution with bowel after performing a supratrigonal cystectomy [354], to create a low-pressure reservoir, is indicated in patients with a severely thick and fibrotic bladder wall [140]. Intermittent catheterisation may become necessary after this procedure. The long-term scientific evidence shows that bladder augmentation is a highly successful procedure that stabilises renal function and prevents anatomical deterioration; however, lifelong follow-up is essential in this patient group given the significant morbidity associated with this procedure [355, 358].

3.4.3.5 Urinary diversion

When no other therapy is successful, urinary diversion must be considered for the protection of the UUT and for the patient's QoL [140].

Continent diversion: This should be the first choice for urinary diversion. Patients with limited dexterity may prefer a stoma instead of using the urethra for catheterisation. For cosmetic reasons, the umbilicus is often used for the stoma site [359-364]. A systematic review of the literature concluded that continent catheterisable tubes/stomas are an effective treatment option in neuro-urological patients unable to perform intermittent self-catheterisation through the urethra [365]. However, the complication rates were significant with 85/213 post-operative events requiring re-operation [365]. Tube stenosis occurred in 4-32% of the cases. Complications related to concomitant procedures (augmentation cystoplasty, pouch) included neovesicocutaneous fistulae (3.4%), bladder stones (20-25%), and bladder perforations (40%). In addition, data comparing HRQoL before and after surgery were not reported [365].

Incontinent diversion: If catheterisation is impossible, incontinent diversion with a urine-collecting device is indicated. Ultimately, it could be considered in patients who are wheelchair bound or bed-ridden with intractable and untreatable incontinence, in patients with LUT destruction, when the UUT is severely compromised, and in patients who refuse other therapy [140]. An ileal segment is used for the deviation in most cases [140, 366-369]. Patients gain better functional status and QoL after surgery [370].

Undiversion: Long-standing diversions may be successfully undiverted or an incontinent diversion changed to a continent one with the emergence of new and better techniques for control of detrusor pressure and incontinence [140]. The patient must be carefully counselled and must comply meticulously with the instructions [140]. Successful undiversion can then be performed [371].

3.4.3.6 Summary of evidence and recommendations for surgical treatment

Summary of evidence	LE
Bladder augmentation is an effective option to decrease detrusor pressure and increase bladder capacity, when all less-invasive treatment methods have failed.	3
Urethral sling placement is an established procedure, with acceptable medium- to long-term results, in women with the ability to self-catheterise.	3
Artificial urinary sphincter insertion is a viable option, with acceptable long-term outcomes, in males. The complication and re-operation rates are higher in neuro-urological patients; therefore, patients must be adequately informed regarding the success rates as well as the complications that may occur following the procedure.	3

Recommendations	Strength rating
Perform bladder augmentation in order to treat refractory neurogenic detrusor overactivity.	Strong
Place an autologous urethral sling in female patients with neurogenic stress urinary incontinence who are able to self-catheterise.	Strong
Insert an artificial urinary sphincter in male patients with neurogenic stress urinary incontinence.	Strong

3.5 Urinary tract infection in neuro-urological patients

3.5.1 Epidemiology, aetiology and pathophysiology

Urinary tract infection is the onset of signs and/or symptoms accompanied by laboratory findings of a UTI (bacteriuria, leukocyturia and positive urine culture) [360]. There are no evidence-based cut-off values for the quantification of these findings. The published consensus is that a significant bacteriuria in persons performing IC is present with $> 10^2$ cfu/mL, $> 10^4$ cfu/mL in clean-void specimens and any detectable concentration in suprapubic aspirates. Regarding leukocyturia, ten or more leukocytes in centrifuged urine samples per microscopic field (400x) are regarded as significant [360].

The pathogenesis of UTI in neuro-urological patients is multifactorial. Male gender seems to be a risk factor for febrile UTI [372]. Several etiological factors have been described: altered intrinsic defence mechanisms, impaired washout and catheterisation [373]. Poor glycemic control has been established as a risk factor for UTI in women with type 1 diabetes [374]. However, the exact working mechanisms remain unknown. The presence of asymptomatic bacteriuria in SCI patients is higher than in the general population, and varies depending on bladder management. Prevalence of bacteriuria in those performing clean IC varies from 23-89% [375]. Sphincterotomy and condom catheter drainage has a 57% prevalence [376]. Asymptomatic bacteria should not be routinely screened for in this population [377].

Individuals with neuro-urological symptoms, especially those with SCI, may have other signs and symptoms in addition to or instead of traditional signs and symptoms of a UTI in able-bodied individuals. Other problems, such as AD, may develop or worsen due to a UTI [225]. The most common signs and symptoms suspicious of a UTI in those with neuro-urological disorders are fever, new onset or increase in incontinence, including leaking around an indwelling catheter, increased spasticity, malaise, lethargy or sense of unease, cloudy urine with increased urine odour, discomfort or pain over the kidney or bladder, dysuria, or AD [225, 378]. New incontinence is the most specific symptom, whereas cloudy and foul smelling urine has the highest positive predictive value for UTI diagnosis [379].

3.5.2 ***Diagnostic evaluation***

Urine culture and urinalysis are the optimum tests for the diagnosis of UTI in neuro-urological patients. A dipstick test may be more useful to exclude than to prove UTI [380, 381]. As bacterial strains and resistance patterns in persons with neuro-urological disorders may differ from those of able-bodied patients, microbiologic testing is mandatory [382].

3.5.3 ***Disease management***

Bacteriuria in patients with neuro-urological disorders should not be treated. Treatment of asymptomatic bacteriuria results in significantly more resistant bacterial strains without improving the outcome [383]. Urinary tract infections in persons with neuro-urological disorders are by definition a complicated UTI; therefore, single-dose treatment is not advised. There is no consensus in the literature about the duration of treatment as it depends on the severity of the UTI and the involvement of kidneys and the prostate. Generally, a five to seven day course of antibiotic treatment is advised, which can be extended up to fourteen days according to the extent of the infection [383]. The choice of antibiotic therapy should be based on the results of the microbiologic testing. If immediate treatment is mandatory (e.g. fever, septicaemia, intolerable clinical symptoms, extensive AD), the choice of treatment should be based on local and individual resistance profiles [384]. In patients with afebrile UTI, an initial non-antibiotic treatment may be justified [385, 386].

3.5.3.1 Recurrent UTI

Recurrent UTI in patients with neuro-urological disorders may indicate suboptimal management of the underlying functional problem, e.g. high bladder pressure during storage and voiding, incomplete voiding or bladder stones. The improvement of bladder function, by treating DO by botulinum toxin A injection in the detrusor [387], and the removal of bladder stones or other direct supporting factors, especially indwelling catheters, as early as possible, are mandatory [382].

3.5.3.2 Prevention

If the improvement of bladder function and removal of foreign bodies/stones is not successful, additional UTI prevention strategies should be utilised. In a meta-analysis the use of hydrophilic catheters was associated with a lower rate of UTI [225]. Bladder irrigation has not been proven effective [388].

Various medical approaches have been tested for UTI prophylaxis in patients with neuro-urological disorders. The benefit of cranberry juice or probiotics for the prevention of UTI could not be demonstrated in RCTs [389, 390]. Methenamine hippurate is not effective in individuals with neuro-urological symptoms [391]. There is no sufficient evidence to support the use of L-methionine for urine acidification to prevent recurrent UTI [392]. There is only weak evidence that oral immunotherapy reduces bacteriuria in patients with SCI [393] and that recurrent UTIs are reduced [394]. Low-dose, long-term, antibiotic prophylaxis can reduce UTI frequency, but increases bacterial resistance and is therefore not recommended [383].

Weekly cycling of antibiotic prophylaxis provided long-term positive results, but the results of this trial need to be confirmed in further studies [395]. Another possible future option, the inoculation of apathogenic *Escherichia coli* strains into the bladder, has provided positive results in initial studies, but because of the paucity of data [396], cannot be recommended as a treatment option. There is initial evidence that homeopathic treatment can decrease UTI frequency [397]. In addition, intravesical gentamycin instillations can reduce UTI frequency without increasing the number of multi-resistant bacteria [398].

In summary, based on the criteria of evidence-based medicine, there is currently no preventive measure for recurrent UTI in patients with neuro-urological disorders that can be recommended without limitations. Therefore, individualised concepts should be taken into consideration, including immunostimulation, phytotherapy and complementary medicine [399]. Prophylaxis in patients with neuro-urological disorders is important to pursue, but since there are no data favouring one approach over another, prophylaxis is essentially a trial and error approach.

*3.5.4 **Summary of evidence and recommendations for the treatment of UTI***

Summary of evidence	LE
Treatment of asymptomatic bacteriuria results in significantly more resistant bacterial strains without improving patient outcome.	1a
Low-dose, long-term, antibiotic prophylaxis does not reduce UTI frequency, but increases bacterial resistance.	2a
Recurrent UTI in patients with neuro-urological disorders may indicate suboptimal management of the underlying functional problem. Improvement of bladder function as early as possible is mandatory.	3
There is currently no preventive measure for recurrent UTI in patients with neuro-urological disorders that can be recommended without limitations.	3

Recommendations	Strength rating
Do not screen for or treat asymptomatic bacteriuria in patients with neuro-urological disorders.	Strong
Avoid the use of long-term antibiotics for recurrent urinary tract infections (UTIs).	Strong
In patients with recurrent UTI, optimise treatment of neuro-urological symptoms and remove foreign bodies (e.g. stones, indwelling catheters) from the urinary tract.	Strong
Individualise UTI prophylaxis in patients with neuro-urological disorders as there is no optimal prophylactic measure available.	Strong

3.6 Sexual function and fertility

These Guidelines specifically focus on sexual dysfunction and infertility in patients with a neurological disease [400, 401]. Non-neurogenic, male sexual dysfunction and infertility are covered in separate EAU Guidelines [402, 403]. In neuro-urological patients sexual problems can be identified at three levels: primary (direct neurological damage), secondary (general physical disabilities) and tertiary (psychosocial and emotional issues) sexual dysfunction [404]. Adopting a systematic approach, such as the PLISSIT model (Permission, Limited Information, Specific Suggestions and Intensive Therapy) [405], provides a framework for counselling and treatment involving a stepwise approach to the management of neurogenic sexual dysfunction. Sexual dysfunction is associated with neurogenic LUT dysfunction in patients with MS [406] and SB [407]. Although various patient reported outcome measures (PROMs) are available to evaluate sexual function, the evidence for good PROMs is limited and studies with high methodological quality are needed [408].

*3.6.1 **Erectile dysfunction***

3.6.1.1 Phosphodiesterase type 5 inhibitors (PDE5Is)

Phosphodiesterase type 5 inhibitors (PDE5Is) are recommended as first-line treatment in neurogenic ED [400, 401]. In SCI patients, tadalafil, vardenafil and sildenafil have all improved retrograde ejaculation and improved erectile function and satisfaction on IIEF-15. Tadalafil 10 mg was shown to be more effective than sildenafil 50 mg. All currently available PDE5Is appear to be effective and safe, although there are no high level evidence studies in neuro-urological patients investigating the efficacy and side effects across different PDE5Is, dosages and formulations [409].

For MS patients two studies reported significant improvement in ED when using sildenafil and tadalafil. One study; however, showed no improvement in ED with sildenafil.

In PD normal erectile function was described in over half of the patients using sildenafil 100 mg and a significant improvement in IIEF-15 score was found compared to placebo. While most neuro-urological patients require long-term therapy for ED some have a low compliance rate or stop therapy because of side effects [410, 411], most commonly headache and flushing [401]. In addition, PDE5Is may induce relevant hypotension in patients with tetraplegia/high-level paraplegia and multiple system atrophy [410, 411]. As a prerequisite for successful PDE5I-therapy, some residual nerve function is required to induce erection. Since many patients with SCI use on-demand nitrates for the treatment of AD, they must be counselled that PDE5Is are contraindicated when using nitrate medication.

3.6.1.2 Drug therapy other than PDE5Is

Fampridine to treat neurogenic spasticity has been shown to be beneficial in improving ED in two domains of the IIEF-15 in SCI and MS patients, however, with a significant discontinuation rate due to severe adverse

events [412]. Sublingual apomorfine was shown to have poor results on ED in SCI patients and side-effects in half of the patients [413]. In PD pergolide mesylate showed a significant improvement in IIEF-15 scores up to twelve months follow-up [414].

3.6.1.3 Mechanical devices

Mechanical devices (vacuum tumescence devices and penile rings) may be effective but are less popular [415-419].

3.6.1.4 Intracavernous injections and intraurethral application

Patients not responding to oral drugs may be offered intracavernous injections (alprostadil, papaverine and phentolamine) that have been shown to be effective in a number of neurological conditions, including SCI, MS, and diabetes mellitus [420-426], but their use requires careful dose titration and some precautions. Complications of intracavernous drugs include pain, priapism and corpora cavernosa fibrosis.

Intracavernous vasoactive drug injection is the first-line therapeutic option in patients taking nitrate medications, as well as those with concerns about drug interactions with PDE5Is, or in whom PDE5Is are ineffective. The impact of intracavernous injections on ejaculation and orgasmic function, their early use for increasing the recovery rate of a spontaneous erection, and their effectiveness and tolerability in the long-term are unclear [410]. Intra-urethral alprostadil application is an alternative, but a less effective, route of administration [422, 427].

3.6.1.5 Sacral neuromodulation

Sacral neuromodulation for LUT dysfunction may improve sexual function; however, high level evidence studies are lacking.

3.6.1.6 Penile prostheses

Penile prostheses may be considered for treatment of neurogenic ED when all conservative treatments have failed. At a mean follow-up of seven years 83.7% of patients with SCI were able to have sexual intercourse [401]. Serious complications, including infection and prosthesis perforation, may occur in about 10% of patients, depending on implant type [428-430].

3.6.1.7 Summary of evidence and recommendations for erectile dysfunction

Summary of evidence	**LE**
The long-term efficacy and safety of oral PDE5Is for the treatment of ED is well documented.	1b
Intracavernous vasoactive drug injections have been shown to be effective in a number of neurological conditions, including SCI and MS; however, their use requires careful dose titration and precautions.	3
Mechanical devices (vacuum tumescence devices and penile rings) may be effective but are less popular.	3
Reserve penile prostheses for selected patients, those in which all conservative treatments have failed, with neurogenic ED.	4

Recommendations	**Strength rating**
Prescribe oral phosphodiesterase type 5 inhibitors as first-line medical treatment in neurogenic erectile dysfunction (ED).	Strong
Give intracavernous injections of vasoactive drugs (alone or in combination) as second-line medical treatment in neurogenic ED.	Strong
Offer mechanical devices such as vacuum devices and rings to patients with neurogenic ED.	Strong

3.6.2 ***Male fertility***

Male fertility can be compromised in the neurological patient by ED, ejaculation disorder, impaired sperm quality or various combinations of these three disorders. Among the major conditions contributing to neurogenic infertility are pelvic and retroperitoneal surgery, diabetes mellitus, SB, MS and SCI [431]. Erectile dysfunction is managed as described previously. Retrograde ejaculation may be reversed by sympathomimetic agents contracting the bladder neck, including imipramine, ephedrine, pseudoephedrine, and phenylpropanolamine [431]. The use of a balloon catheter to obstruct the bladder neck may be effective in obtaining antegrade ejaculation [432]. If antegrade ejaculation is not achieved, the harvest of semen from the urine may be considered [433].

Prostatic massage is safe and easy to use for obtaining semen in men with lesions above Th 10 [434]. In several patients, vibrostimulation or transrectal electroejaculation are needed for sperm retrieval [431, 435, 436]. Semen retrieval is more likely with vibrostimulation in men with lesions above Th 10 [437-439]. In men with SCI, especially at or above Th 6, AD might occur during sexual activity and ejaculation [440, 441]; patients at risk and fertility clinics must be informed and aware of this potentially life-threatening condition. In SCI patients the use of oral midodrine can improve sperm retrieval at vibrostimulation [442].

In men with MS, use of disease modifying drugs during the conception phase, has not been associated with altered pregnancy outcomes [443]. Surgical procedures, such as, microsurgical epididymal sperm aspiration (MESA) or testicular sperm extraction (TESE), may be used if vibrostimulation and electroejaculation are not successful [444, 445]. Pregnancy rates in patients with SCI are lower than in the general population, but since the introduction of intracytoplasmic sperm injection (ICSI), men with SCI now have a good chance of becoming biological fathers [446-448].

3.6.2.1 Sperm quality and motility

The following has been reported on sperm quality and motility:

- bladder management with clean IC may improve semen quality compared to indwelling catheterisation, reflex voiding or bladder expression [449];
- in SCI patients sperm quality decreases at the early post traumatic phase demonstrating lower spermatozoid vitality (necrospermia), reduced motility (asthenospermia) and leucospermia [444];
- long-term valproate treatment for epilepsy negatively influences sperm count and motility [450];
- vibrostimulation produces samples with better sperm motility than electrostimulation [451, 452];
- electroejaculation with interrupted current produces better sperm motility than continuous current [453];
- freezing of sperm is unlikely to improve fertility rates in men with SCI [454].

3.6.2.2 Summary of evidence and recommendations for male fertility

Summary of evidence	**LE**
Vibrostimulation and transrectal electroejaculation have been shown to be effective for sperm retrieval in neuro-urological patients.	1b
Surgical procedures, such as, microsurgical epididymal sperm aspiration or testicular sperm extraction, may be used if vibrostimulation and electroejaculation are not successful.	3
In men with SCI at or above Th 6, AD might occur during sexual activity and ejaculation.	3

Recommendations	**Strength rating**
Perform vibrostimulation and transrectal electroejaculation for sperm retrieval in men with spinal cord injury.	Strong
Perform microsurgical epididymal sperm aspiration, testicular sperm extraction and intracytoplasmic sperm injection after failed vibrostimulation and/or transrectal electroejaculation in men with spinal cord injury.	Strong
Counsel men with spinal cord injury at or above Th 6 and fertility clinics about the potentially life-threatening condition of autonomic dysreflexia.	Strong

*3.6.3 **Female sexuality***

The most relevant publications on neurogenic female sexual dysfunction are in women with SCI and MS. After SCI, about 65-80% of women continue to be sexually active, but to a much lesser extent than before the injury, and about 25% report a decreased satisfaction with their sexual life [455-458]. Although sexual dysfunction is very common in women with MS, it is still often overlooked by medical professionals [459, 460].

The greatest physical barrier to sexual activity is UI. A correlation has been found between the urodynamic outcomes of low bladder capacity, compliance and high maximum detrusor pressure and sexual dysfunction in MS patients. Problems with positioning and spasticity affect mainly tetraplegic patients. Peer support may help to optimise the sexual adjustment of women with SCI in achieving a more positive self-image, self-esteem and feelings of being attractive to themselves and others [455, 461-463].

The use of specific drugs for sexual dysfunction is indicated to treat inadequate lubrication. Data on sildenafil for treating female sexual dysfunction are poor and controversial [401]. Although good evidence exists that psychological interventions are effective in the treatment of female hypoactive sexual desire disorder and female orgasmic disorder [464], there is a lack of high-level evidence studies in the neurological population.

Neurophysiological studies have shown that women with the ability to perceive Th 11-L2 pin-prick sensations may have psychogenic genital vasocongestion. Reflex lubrication and orgasm is more prevalent in women with SCI who have preserved the sacral reflex arc (S2-S5), even when it has not been shown in an individual woman that a specific level and degree of lesion is the cause of a particular sexual dysfunction. In SCI women with a complete lesion of the sacral reflex, arousal and orgasm may be evoked through stimulation of other erogenous zones above the level of lesions [465-467].

Sacral neuromodulation for LUT dysfunction may improve sexual function but high-evidence studies are lacking [401].

Women with SCI reported dissatisfaction with the quality and quantity of sexuality-related rehabilitation services and were less likely to receive sexual information than men [465, 468, 469].

*3.6.4 **Female fertility***

There are few studies on female fertility in neurological patients. More than a third (38%) of women with epilepsy had infertility and the relevant predictors were exposure to multiple (three or more) antiepileptic drugs, older age and lower education [470].

Although it seems that the reproductive capacity of women with SCI is only temporarily affected by SCI with cessation of menstruation for approximately six months after SCI [471], there are no high-level evidence studies. About 70% of sexually active women use some form of contraception after injury, but fewer women use the birth control pill compared to before their injury [472].

Women with SCI are more likely to suffer complications during pregnancy, labour and delivery compared to able-bodied women. Complications of labour and delivery include bladder problems, spasticity, pressure sores, anaemia, and AD [473-477]. Obstetric outcomes include higher rates of Caesarean sections and an increased incidence of low birth-weight babies [472, 475-477].

Epidural anaesthesia is chosen and effective for most patients with AD during labour and delivery [478, 479].

There is very little published data on women's experience of the menopause following SCI [480]. Women with MS who plan a pregnancy should evaluate their current drug treatment with their treating physician [481-483]. Clinical management should be individualised to optimise both the mother's reproductive outcomes and MS course [482-484].

3.6.4.1 Summary of evidence and recommendation for female sexuality and fertility

Summary of evidence	**LE**
Data on specific drugs for treating female sexual dysfunction are poor and controversial.	4
There are limited numbers of studies on female fertility in neurological patients, clinical management should be individualised to optimise both the mother's reproductive outcomes and medical condition.	4

Recommendations	**Strength rating**
Do not offer medical therapy for the treatment of neurogenic sexual dysfunction in women.	Strong
Take a multidisciplinary approach, tailored to individual patient's needs and preferences, in the management of fertility, pregnancy and delivery in women with neurological diseases.	Strong

3.7 Follow-up

*3.7.1 **Introduction***

Neuro-urological disorders are often unstable and the symptoms may vary considerably, even within a relatively short period. Regular follow-up is therefore necessary to assess the UUT [138].

Depending on the type of the underlying neurological pathology and the current stability of the neuro-urological symptoms, the interval between initial investigations and control diagnostics may vary and in many cases should not exceed one to two years. In high-risk neuro-urological patients this interval should be much shorter. Urinalysis should be performed only when patients present with symptoms [485]. The UUT should be checked by ultrasonography at regular intervals in high-risk patients; about once every six months [6, 486]. In these patients, physical examination and urine laboratory should take place every year [6, 486]. In MS patients higher scores on the Expanded Disability Status Scale (EDSS) are associated with risk factors for UUT deterioration [53]. A urodynamic investigation should be performed as a diagnostic baseline, and repeated during follow-up, more frequently in high-risk patients [6, 486]. In addition, bladder wall thickness can be measured on

ultrasonography as an additional risk assessment for upper tract damage [487], although a 'safe' cut-off threshold for this has not been agreed [488]. The utility of DMSA for follow-up of neuro-urological patients has not been fully evaluated [489]. Any significant clinical change warrants further, specialised, investigation [6, 486]. However, there is a lack of high level evidence studies on this topic and every recommendation must be viewed critically in each individual neuro-urological patient [138].

The increased prevalence of muscle invasive bladder cancer in neuro-urological patients also warrants long-term follow-up [490]. The exact frequency of cystoscopy with or without cytology remains unknown, but presence of risk factors similar to the general population should trigger further investigation [485].

Adolescent patients with neurological pathology are at risk of being lost to follow-up during the transition to adulthood. It is important that a standardised approach during this transition is adopted to improve follow-up and specific treatment during adult life [491].

*3.7.2 **Summary of evidence and recommendations for follow-up***

Summary of evidence	**LE**
Neuro-urological disorders are often unstable and the symptoms may vary considerably, therefore, regular follow-up is necessary.	4

Recommendations	**Strength rating**
Assess the upper urinary tract at regular intervals in high-risk patients.	Strong
Perform a physical examination and urine laboratory every year in high-risk patients.	Strong
Any significant clinical changes should instigate further, specialised, investigation.	Strong
Perform urodynamic investigation as a mandatory baseline diagnostic intervention in high-risk patients at regular intervals.	Strong

3.8 Conclusions

Neuro-urological disorders have a multi-faceted pathology. They require an extensive and specific diagnosis before one can embark on an individualised therapy, which takes into account the medical and physical condition of the patient and the patient's expectations about their future. The urologist can select from a wealth of therapeutic options, each with its own pros and cons. Notwithstanding the success of any therapy embarked upon, close surveillance is necessary for the patient's entire life.

These Guidelines offer you expert advice on how to define the patient's neuro-urological symptoms as precisely as possible and how to select, together with the patient, the appropriate therapy. This last choice, as always, is governed by the golden rule: as effective as needed, as non-invasive as possible.

5. CONFLICT OF INTEREST

All members of the Neuro-urology working group have provided disclosure statements of all relationships that they have that might be perceived as a potential source of a conflict of interest. This information is publically accessible through the European Association of Urology website: http://uroweb.org/guideline. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative and travel and meeting expenses. No honoraria or other reimbursements have been provided.

6. CITATION INFORMATION

The format in which to cite the EAU Guidelines will vary depending on the style guide of the journal in which the citation appears. Accordingly, the number of authors or whether, for instance, to include the publisher, location, or an ISBN number may vary.

The compilation of the complete Guidelines should be referenced as:
EAU Guidelines. Edn. presented at the EAU Annual Congress Amsterdam 2020. ISBN 978-94-92671-07-3.

If a publisher and/or location is required, include:
EAU Guidelines Office, Arnhem, The Netherlands. http://uroweb.org/guidelines/compilations-of-all-guidelines/

References to individual guidelines should be structured in the following way:
Contributors' names. Title of resource. Publication type. ISBN. Publisher and publisher location, year.

TABLE OF CONTENTS PAGE

1. INTRODUCTION

1.1 Aims and Objectives

The European Association of Urology (EAU) Sexual and Reproductive Health Guidelines aim to provide a comprehensive overview of the medical aspects relating to sexual and reproductive health in adult males. These Guidelines cover the former EAU guidelines on Male Sexual Dysfunction, Male Infertility and Male Hypogonadism.

It must be emphasised that guidelines present the best evidence available to the experts. However following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The EAU Sexual and Reproductive Health Guidelines panel consists of an international multidisciplinary group of urologists, endocrinologists and a psychologist. All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website: http://www.uroweb.org/guideline/sexualandreproductivehealth/.

1.3 Available Publications

Alongside the full text version, a quick reference document (Pocket Guidelines) is available in print and as an app for iOS and android devices. These are abridged versions which may require consultation together with the full text version. All documents can be viewed through the EAU website: http://www.uroweb.org/guideline/sexualandreproductivehealth/.

1.4 Publication History

This document is a new Guideline which includes a comprehensive update of the 2018 versions of Male Sexual Dysfunction, Male Infertility and Male Hypogonadism, along with a number of new topics. Additional sections will be added in the coming year to address priapism and male contraception and vasectomy which were addressed in the 2018 versions.

2. METHODOLOGY

2.1 Methods

For the 2020 Sexual and Reproductive Health Guidelines, new and relevant evidence has been identified, collated and appraised through a structured assessment of the literature. A broad and comprehensive literature search, covering all sections of the Guidelines was performed. Databases searched included Medline, EMBASE, and the Cochrane Libraries, covering a time frame between 2013 and 2018 and restricted to English language publications. Detailed search strategies are available online: http://www.uroweb.org/guideline/sexualandreproductivehealth/.

For each recommendation within the guidelines there is an accompanying online strength rating form, the basis of which is a modified GRADE methodology [1, 2]. Each strength rating form addresses a number of key elements namely:

1. the overall quality of the evidence which exists for the recommendation, references used in this text are graded according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [3];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact of patient values and preferences on the intervention;
6. the certainty of those patient values and preferences.

These key elements are the basis which panels use to define the strength rating of each recommendation. The strength of each recommendation is represented by the words ‘strong’ or ‘weak’ [4]. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative

management strategies, the quality of the evidence (including certainty of estimates), and nature and variability of patient values and preferences.

Additional information can be found in the general Methodology section of this print, and online at the EAU website: http://www.uroweb.org/guideline/. A list of associations endorsing the EAU Guidelines can also be viewed online at the above address.

2.2 Review

Sections of the Sexual and Reproductive Health Guidelines were peer reviewed prior to publication. This is an ongoing process which will continue as the Guidelines is further refined in the coming year.

2.3 Future goals

The results of ongoing and new systematic reviews will be included in the 2021 update of the Sexual and Reproductive Health Guidelines. Systematic reviews planned for 2020 are:

- What is the effectiveness of non-surgical therapies in the treatment of ischaemic priapism in patients with sickle cell disease?
- What is the effectiveness of non-surgical therapies in the management of priapism in patients without sickle cell disease?

3. MALE HYPOGONADISM

3.1 Epidemiology and prevalence of male hypogonadism

Definition: Male hypogonadism is a disorder associated with decreased functional activity of the testes, with decreased production of androgens and/or impaired sperm production [5]. This is caused by poor testicular function or as a result of inadequate stimulation of the testes by the hypothalamic-pituitary axis. Several congenital or acquired disorders causing impaired action of androgens are also described [5]. Hypogonadism may adversely affect multiple organ functions and quality of life (QoL) [6]. Late-onset hypogonadism (LOH) is a clinical condition in the aging male, which, by definition, must comprise both persistent specific symptoms and biochemical evidence of testosterone deficiency [5, 7]. It is a condition frequently diagnosed in the absence of an identifiable classical cause of hypogonadism, which becomes more prevalent with age, usually occurring, but not exclusively, in men over 40 years of age.

Male hypogonadism has also been called *Testosterone Deficiency*; the Panel has agreed to use the term *Male Hypogonadism*, which may better reflect and explain the underlying pathophysiology. Likewise, the Panel has further agreed to continue with the terminology *testosterone therapy* to indicate a therapy with testosterone. The present guidelines will specifically address the management of adult male hypogonadism also called LOH. Some insights related to congenital or pre-pubertal hypogonadism are also provided and summarised where applicable.

The prevalence of hypogonadism increases with age and the major causes are central obesity, co-morbidities (e.g., diabetes) and overall poor health [8]. In healthy aging men there is only a small gradual decline in testosterone; up to the age of 80 years, age accounts for a relatively low percentage of hypogonadism [8]. In men aged between 40-79 years the incidence of symptomatic hypogonadism varies between 2.1-5.7% [9-11]. The incidence of hypogonadism has been reported to be 12.3 and 11.7 cases per 1,000 people per year [9, 12].

There is a high prevalence of hypogonadism within specific populations, including patients with type 2 diabetes (T2DM), metabolic syndrome (MetS), obesity, cardiovascular disease (CVD), chronic obstructive pulmonary disease (COPD), renal disease and cancer [11]. Low testosterone levels are common in men with T2DM [13] and a high prevalence of hypogonadism (42%) has been reported in T2DM patients [14].

Klinefelter's syndrome, a trisomy associated with a 47,XXY karyotype, is the most prevalent genetic cause of primary hypogonadism (hypergonadotropic hypogonadism), with a global prevalence of 1/500-1,000 live male births [15-17]. However, less than 50% of individuals with Klinefelter syndrome are diagnosed in life [18].

3.1.1 Body Composition and Metabolic Profile

Low testosterone levels are common in men with obesity. Male hypogonadism is associated with a greater percentage of fat mass and a lesser lean mass compared to men with adequate testosterone levels [19]. Much evidence has documented that low testosterone is strongly associated with an increased visceral adiposity, but it also leads to deposition of lipids in the liver and muscle and is associated with atherosclerosis [19]. *In vitro* studies suggest that hypogonadism impairs glucose and triglyceride uptake into subcutaneous fat depots [19]. This enhances the uptake of glucose and triglycerides into ectopic fat depots as described above.

Testosterone therapy has been associated with a reduced percentage of body fat and an increase of lean body mass [20]. Data from a registry study has suggested that over a period of eight years, testosterone therapy with long-acting intramuscular testosterone undecanoate was associated with a substantial but gradual loss of weight along with a reduction in waist circumference [21]. Testosterone also reduces liver fat content and muscle fat stores [19].

*3.1.2 **Metabolic Syndrome/Type 2 Diabetes***

Metabolic Syndrome (MetS) is characterised by a number of specific components, including increased waist circumference, dyslipidaemia, hypertension, and impaired glucose tolerance. Hypogonadism is associated with central obesity, hyperglycaemia, insulin resistance and dyslipidaemia (low HDL-cholesterol, raised total and LDL-cholesterol and triglycerides), hypertension and a predisposition to T2DM, which are all components of MetS [22].

A number of randomised controlled trials (RCTs) have shown that testosterone therapy might improve insulin resistance, hyperglycaemia and lower cholesterol and LDL-cholesterol [23-27]. Evidence suggests that testosterone therapy in hypogonadal T2DM improves glycaemic control in some RCTs and registry trials; however, there is no conclusive evidence from RCTs and meta-analyses studies [24, 28, 29]. Recently, a registry study reported that testosterone therapy is associated in time with remission of T2DM [28]. HDL-cholesterol may decrease, remain unchanged or increase with testosterone therapy. Testosterone therapy in men with MetS and low testosterone has also been shown to reduce mortality compared to untreated men [30, 31] although no conclusive evidence is available.

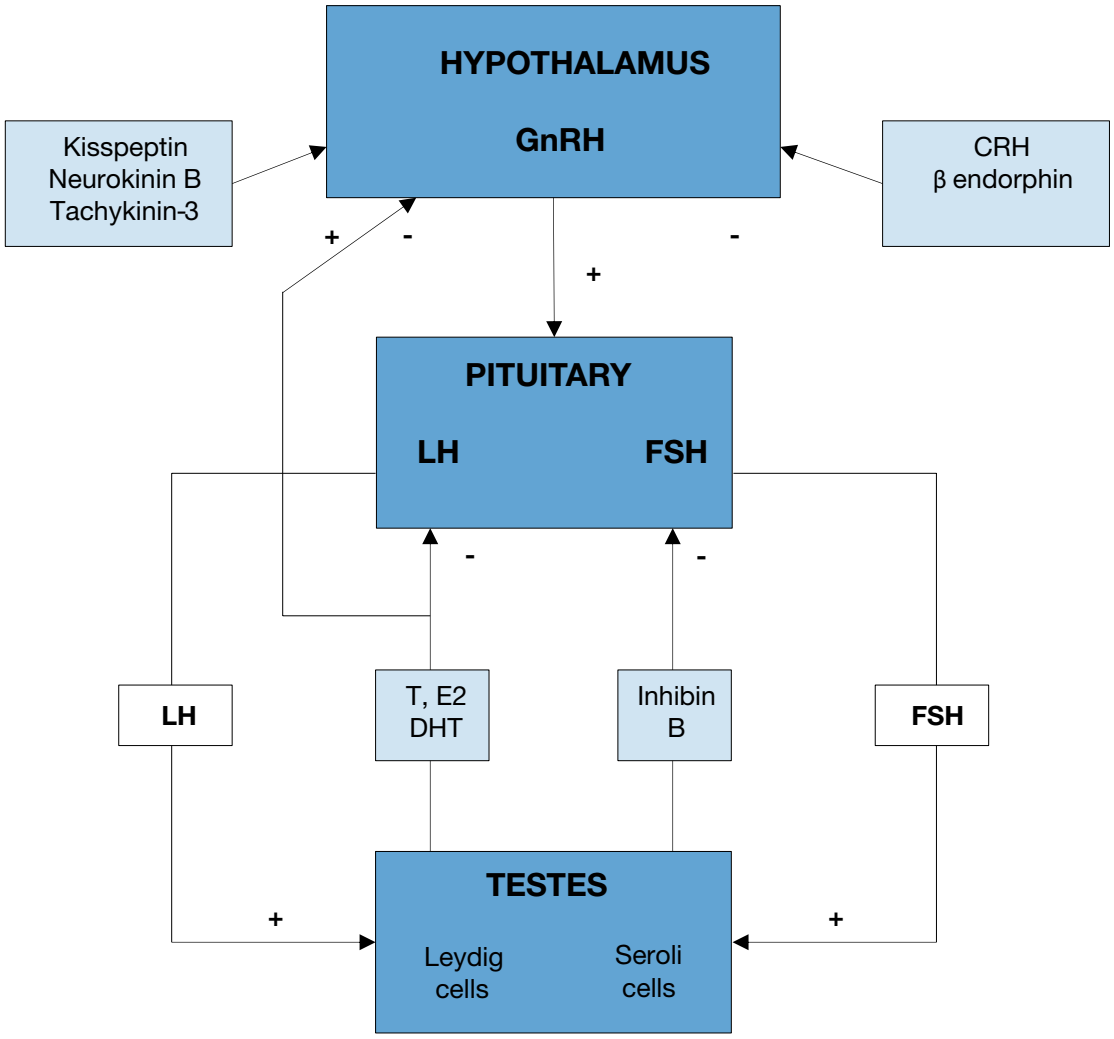
Erectile dysfunction (ED) is common in men with MetS and T2DM (up to 70% of patients). The causes of ED are multifactorial and 30% of men with ED have co-existing testosterone deficiency. Some evidence has suggested that for patients with T2DM this has been demonstrated only to be the case in men with clearly reduced testosterone levels (< 8mmol/L [2.31 ng/mL]) [32]. From a pathophysiological point of view, it has been reported that this is because ED is predominantly due to vascular and neuropathic disease, therefore not likely to be the case in those men who do not have an established vascular disease. Therefore, men presenting with ED should be screened for MetS. Likewise, patients with ED and diabetes may be offered testosterone measurement.

Randomised placebo-controlled trials of testosterone therapy in T2DM have demonstrated improved sexual desire and satisfaction, but not erectile function [24, 32]. The presence of multi-comorbidities in this group of patients may confound the response to testosterone alone.

3.2 Physiology of testosterone production

The pituitary gland regulates testis activity, through the secretion of luteinising hormone (LH), which regulates testosterone production in Leydig cells and follicle-stimulating hormone (FSH), which mainly controls sperm production in seminiferous tubules [33, 34]. The production and secretion of gonadotropins is stimulated by hypothalamic gonadotropin releasing hormone (GnRH) and inhibited by a negative feedback mediated by the central action of sex steroids and inhibin B (Figure 1) [33, 34]. Gonadotropin releasing hormone is secreted in a pulsatile manner and negatively controlled by the activity of other hypothalamic neurons, including corticotrophin releasing hormone (CRH) and β endorphin neurons [33, 34]. Conversely, kisspeptin-1 (Kiss-1) neurons, neurokinin-B or tachykinin-3 are involved in GnRH stimulation. Finally, leptin is also involved in the activation of Kiss-1 signaling [35]. About 25 mg of testosterone is present in the normal testes, and, on average, 5-10 mg of testosterone are secreted daily [33, 34]. The testis also produces lesser amounts of other androgens such as androstenedione and dehydroepiandrosterone (DHT). In addition, a small amount of extra-gonadal testosterone is derived from circulating weak adrenal androgen precursor dehydroepiandrosterone (DHEA), although its specific contribution to daily testosterone production is limited in men [36, 37]. In physiological terms, DHT formation accounts for about 6-8% of testosterone metabolism, and the ratio of plasma testosterone/DHT is approximately 1:20 [33, 34]. Finally, testosterone and its precursor, Δ4 androstenedione, can be aromatised through P450 aromatase to other bioactive metabolites, such as oestrone (E1) and 17-β-estradiol (E2), with a daily production of about 45 μg [33, 34]. Furthermore, Leydig cells, can also directly produce and release into the bloodstream a small amount of oestrogens, with a daily production rate of about 5-10 μg (up to 20% of circulating oestrogens) [38].

Figure 1: Physiology of testosterone production



GnRH = gonadotropin releasing hormone; LH = luteinising hormone; FSH = follicle-stimulating hormone; T = testosterone; E2 = 7-β-estradiol; DHT = dehydroepiandrosterone; CRH = corticotrophin releasing hormone.

*3.2.1 **Circulation and transport of testosterone***

In normal men 60% to 70% of circulating testosterone is bound to the high affinity sex hormone-binding globulin (SHBG), a protein produced by the liver, which prevents its bound testosterone sub-fraction from biological action. The remaining circulating testosterone binds lower affinity, high-capacity binding protein sites, (albumin, α-1 acid glycoprotein and corticosteroid binding protein), and only 1%-2% of testosterone remains non-protein bound [39]. There is a general agreement that testosterone bound to lower affinity proteins can easily dissociate in the capillary bed of many organs accounting for so-called 'bioavailable' testosterone [39]. It is important to recognise that several clinical conditions and aging itself can modify SHBG levels, thus altering circulating total testosterone levels (Table 1). Therefore, if not recognised, these factors could lead to an incorrect estimation of male androgen status. Therefore, when indicated (see Table 1) SHBG should be tested and free testosterone calculated.

Table 1: Main factors associated with an increase or reduction of SHBG circulating levels

SHBG increase	Drugs: anticonvulsant, oestrogens, thyroid hormone Hyperthyroidism Hepatic disease Aging Smoking AIDS/HIV
SHBG decrease	Drugs: GH, glucocorticoids, testosterone, anabolic androgenic steroids Hypothyroidism Obesity Acromegaly [40] Cushing Disease Insulin resistance (MetS/T2DM) o non-alcoholic fatty liver disease (NAFLD), Nephrotic syndrome

*3.2.2 **Androgen receptor (AR)***

Testosterone and DHT exert their biological action through the activation of a specific nuclear receptor. The AR gene is localised on the X chromosome (Xq11-12), encoded in eight exons [41]. Exon 1 includes two polymorphic trinucleotide repeat segments encoding polyglutamine (CAG) and polyglycine (GGN) tracts in the N-terminal transactivation domain of its protein. It has been established that the activity of the AR is inversely associated with the length of the CAG repeat chains [41]. However, the specific role of AR CAG repeat number in relation to hypogonadal symptoms or to clinical management of testosterone deficiency remains unclear [42, 43]. It has been shown in an RCT that a higher CAG repeat number is positively associated with a change in fasting insulin, triglyceride and diastolic blood pressure, demonstrating the more sensitive the receptor the greater the benefit [44].

3.3 Role of testosterone in male sexual and reproductive health

*3.3.1 **Sexual development and maturation***

Testosterone production in the foetal testis starts between the eighth and ninth week of gestation after the expression of the SRY (Sex-determining Region Y) gene, which regulates the organisation of the undifferentiated gonadal ridge into the testis [45]. During the first trimester, the testes drive the virilisation of internal and external genitalia through placental human chorionic gonadotropin (hCG) stimulated androgen secretion by Leydig cells. During foetal life, testosterone mainly controls the differentiation of internal genitalia and testis descent (regression of gubernaculums testis), whereas DHT is mainly involved in the development of the external male genitalia [46]. During puberty, the reactivation of the hypothalamus-pituitary-gonadal (HPG) axis allows the development of secondary sexual characteristics, spermatogenesis maturation and, along with the contribution of other hormonal axes, the completion of the adolescent growth spurt [5, 47]. Clinical models of aromatase deficiency and oestrogen receptor insensitivity have demonstrated that testosterone conversion to estradiol is essential for epiphyseal closure and growth arrest [48].

*3.3.2 **Sexual function***

Testosterone is involved in the regulation of all steps of the male sexual response. Sexual thoughts and motivations are universally accepted as the most testosterone-dependent aspects of male sexual behaviour [20]. The European Male Aging Study (EMAS), a population-based survey including more than 3,400 subjects aged 40-80 years from eight European countries, showed that sexual symptoms and, in particular, sexual desire impairment, ED and a decreased frequency of morning erections were the most specific symptoms associated with age-depended decline of testosterone [10]. Similar findings were reported in subjects consulting for sexual dysfunctions [49]. Accordingly, several brain areas, including the amygdala, medial preoptic area, paraventricular nucleus of the hypothalamus, and peri-aqueductal grey matter express the AR [49, 50]. Both experimental and clinical studies have documented that testosterone plays a crucial role in regulating penile function. In particular, testosterone controls the structural integrity necessary for penile erection as well as several enzymatic activities within the corpora cavernosa, including a positive action on nitric oxide (NO) formation and a negative influence on the activity of the Ras homolog gene family member A/Rho-associated kinase (RhoA/ROCK) pathways [49, 51]. Testosterone is also involved in penile adrenergic response and cavernous smooth muscle cell turnover [49, 51]. Finally, although some authors have suggested a positive role of testosterone in regulating penile phosphodiesterase 5 (PDE5) expression and activity, other evidence showed a prevalent inhibiting role of oestrogens on this pathway [49, 52].

More limited evidence documented a possible role of testosterone in regulating ejaculatory process acting either at central and peripheral level. Androgen receptors are expressed in several central spinal and super-spinal areas involved in the control of ejaculatory reflex [53]. In addition, the male genital tract expresses NO-PDE5 as well as RhoA/ROCK pathways, which are modulated by testosterone [53].

3.4 Classification and causes of male hypogonadism

Male hypogonadism can be classified according to the origin of the underlying problem into primary, if a consequence of testicular dysfunction, or secondary if due to a pituitary or hypothalamic dysfunction (Table 2).

Primary hypogonadism is also called hypergonadotropic hypogonadism (HH), since the pituitary tries compensating the dysfunctional testis by increasing central stimulation. Conversely, in secondary hypogonadism the testis is inadequately stimulated by gonadotropins resulting in a HH, usually with inappropriately normal or reduced gonadotropin levels [5, 34]. A compensated or subclinical form of hypogonadism, characterised by normal testosterone serum levels and elevated LH production, has also been reported [54]; the clinical significance of the latter condition is unclear [54, 55]. Finally, hypogonadism can also result from a group of several conditions leading to a reduced sensitivity/insensitivity to testosterone and its metabolites (Table 2) [5, 34]. This classification, based on the aetiology of hypogonadism, allows the clinician to adequately select appropriate treatment. In patients with secondary hypogonadism, both fertility and testosterone normalisation can be theoretically achieved with an adequate treatment, whereas in primary hypogonadism only testosterone therapy can be considered, which will impair fertility due to suppression of the hypothalamic pituitary axis (HGP) (Table 2) [5, 34].

In 2017, Grossmann and Matsumoto suggested a new classification of adult male hypogonadism, distinguishing functional versus organic hypogonadism [56]. Accordingly, organic hypogonadism is characterised by any proven pathology affecting the HPG axis and should be treated with the conventional medications (i.e., gonadotropins or TRT); conversely, functional hypogonadism is based on the absence of any recognised organic alterations in the HPG axis and should be treated, first by resolving or improving the associated comorbidities. These Guidelines refer to the validated international classification of adult male hypogonadism.

Table 2: Classification of male hypogonadism

PRIMARY HYPOGONADISM (hypergonadotropic hypogonadism)	
Congenital or developmental disorders	
Common causes	*Uncommon causes*

Klinefelter syndrome	- Rare chromosomal abnormalities
	  - XX male syndrome
	  - 47 XYY syndrome
	  - 48 XXYY syndrome
	- 21 Trisomy (Down syndrome)
	- Noonan syndrome
	- Autosomal translocations[1]
	- Defects of testosterone biosynthesis
	- CAH (testicular adrenal rest tumours)
	- Disorders of sex development (gonadal dysgenesis)
	- LHR gene mutations
	- Myotonic dystrophy (including type I and II)
	- Uncorrected cryptorchidism (including INSL3 and LGR8 mutations)
	- Bilateral congenital anorchia
	- Sickle cell disease
	- Adreno-leukodystrophy

Acquired disorders	
Drug-induced	*Localised problems*
- Chemotherapy agents • Alkylating agents - Methotrexate • Testosterone synthesis inhibitors • Ketoconazole • Aminoglutethimide • Mitotane • Metyrapon	- Bilateral surgical castration or trauma - Testicular irradiation - Orchitis (including mumps orchitis) - Autoimmune testicular failure - Testicular Torsion - Alcohol/Cirrhosis • Environmental Toxins

Systemic diseases/conditions with hypothalamus/pituitary impact	

- Chronic systemic diseases*
- Chronic organ failure*
- Glucocorticoid excess (Cushing syndrome)*
- Aging*
- HIV
	- Malignancies
	  - Lymphoma
	  - Testis cancer
	- Spinal cord injury
	- Vasculitis
	- Infiltrative diseases (amyloidosis; leukaemia)

SECONDARY HYPOGONADISM (hypogonadotropic hypogonadism)	
Congenital or developmental disorders	
Common causes	*Uncommon causes*

- Hemochromatosis*	- Combined hormone pituitary deficiency
	- Idiopathic hypogonadotropic hypogonadism (IHH) with variants:
	  - Normosmic IHH
	  - Kallmann syndrome
	  - Isolated LH β gene mutations
	  - Prader-Willi Syndrome

Acquired disorders	
Drug-induced	*Localised problems*

- Oestrogens
- Testosterone or androgenic anabolic steroids
- Progestogens (including cyproterone acetate)
- Hyperprolactinaemia-induced drugs
- Opiates
  - GnRH agonist or antagonist
  - Glucocorticoids
	- Traumatic brain injury
	- Pituitary neoplasm (micro/macro adenomas)
	- Hypothalamus tumours
	- Pituitary stalk diseases
	- Iatrogenic
	  - Surgical hypophisectomy
	  - Pituitary or cranial irradiation
	- Inflammatory and infectious diseases
	  - Lymphocytic hypophysitis
	  - Pituitary infections
	  - Granulomatous lesions
	  - Sarcoidosis
	  - Wegener's granulomatosis
	  - Other granulomatosis
	  - Encephalitis
	- Langerhans' histiocytosis
	- Hyperprolactinaemia as a consequence of localised problems (hypothalamus-pituitary mass)

Systemic diseases/conditions impacting the hypothalamus/pituitary	

- Chronic systemic diseases*
  - Metabolic diseases
  - HIV infection
  - Chronic organ failure
  - Chronic Inflammatory Arthritis
- Glucocorticoid excess (Cushing syndrome)*
- Eating disorders*
- Endurance exercise
- Acute and critical illness
- Aging*
	- Spinal cord injury
	- Transfusion-related iron overload (β-thalassemia)

ANDROGEN RESISTANCE/DECREASED TESTOSTERONE BIOACTIVITY	
Congenital or developmental disorders	
- Aromatase deficiency - Kennedy diseases (spinal and bulbar muscular atrophy)and other extensions of CAG repeats - Partial or complete androgen insensitivity - 5α reductase type II (5αR) deficiency	
Acquired disorders	
Drug-induced	*Localised problems*

- Drug-induced AR blockage
  - Steroidal antiandrogen
  - Cyproterone acetate
  - Spironolactone
  - Non-steroidal antiandrogen
  - Flutamide
  - Bicalutamide
  - Nilutamide
- Drug-induced 5α reductase (5αR) activity blockade
  - Finasteride
  - Dutasteride
- Drug-induced ER blockade
  - Clomiphene
  - Tamoxifen
  - Raloxifene
- Drug-induced aromatase activity blockade
  - Letrozole
  - Anastrazole
  - Exemestane
- Increased Sex Hormone Binding Protein (SHBG)
	- Celiac disease

** Conditions acting and central and peripheral levels resulting in either primary and secondary hypogonadism*
[1] Different autosomal translocations can cause rare cases of hypogonadism and infertility

3.5 Late-onset hypogonadism

Testosterone production declines as a function of age. The EMAS study reported a 0.4% per annum (log hormone-age) decrease in total testosterone and a 1.3% per annum decline in free testosterone (fT) [8]. Late onset hypogonadism is the term frequently used to describe this phenomenon and the detection of hypogonadism in adulthood, in particular. Evidence has documented that a number of associated diseases and chronic co-morbidities can interfere with the HPG axis leading to the development of primary hypogonadism or, more frequently, secondary hypogonadism in adulthood, thus significantly influencing the physiological age-dependent decline of testosterone. By combining the data from three different waves of the Massachusetts Male Aging Study (MMAS), a population-based, observational study including 1,709 men aged 40-70 years, Mohr *et al.* [57] showed that associated comorbidities and obesity significantly decreased, whereas smoking tended to increase total, free and bio-available testosterone concentrations. Similarly, data derived from the EMAS study confirm these findings [8, 55]. Based upon these data and other evidence, the concept of *functional and organic hypogonadism* has been recently introduced [56]. The diagnosis of functional hypogonadism is based on the exclusion of a classical (organic) aetiology. The main causes of functional hypogonadism are obesity, co-morbidities and aging with the first two of these accounting for the majority of this definition. Inflammatory cytokines released in states of chronic inflammation, and adipocytokines and estradiol in obesity, can suppress the HPG axis. The role of aging up to the age of 80 years seems relatively small [56]. Considering that suppression of HPG axis activity is functional, and potentially reversible by empiric measures, such as weight loss, the need for testosterone therapy has been questioned [56].

*3.5.1 **Diagnostic evaluation***

The phenotype of the hypogonadal patient appears independent of the aetiology causing the problem, but is more often affected by the age of onset of hypogonadism. When androgen deficiency is complete and develops during the foetal life, symptoms can be dramatic, spanning from an almost complete female phenotype (complete androgen insensitivity or enzymatic defects blocking androgen synthesis) to various

defects in virilisation and ambiguous genitalia (micropenis, hypospadias, cryptorchidism) [5, 34]. Delay in puberty with an overall eunochoidal phenotype (scant body hair, high-pitched voice, small testis, penis and prostate) is typical of defects manifesting in the pre- or peri-pubertal period due to milder central (isolated HH) or peripheral defects (such as in Klinefelter syndrome) [5, 34]. When hypogonadism occurs in adulthood, especially in the case of functional hypogonadism, symptoms can be often relatively mild, difficult to recognise and frequently confused with the aging process [5, 34] or with the comorbid chronic conditions. Several non-specific clinical features such as fatigue, weakness, and decreased energy, as well as sexual impairment may be clinical manifestations. The EMAS study showed that a triad of sexual symptoms, including low libido, reduced spontaneous erections and ED, are typically associated with a decrease in testosterone serum levels [10]. Conversely, psychological and physical symptoms were less informative [10].

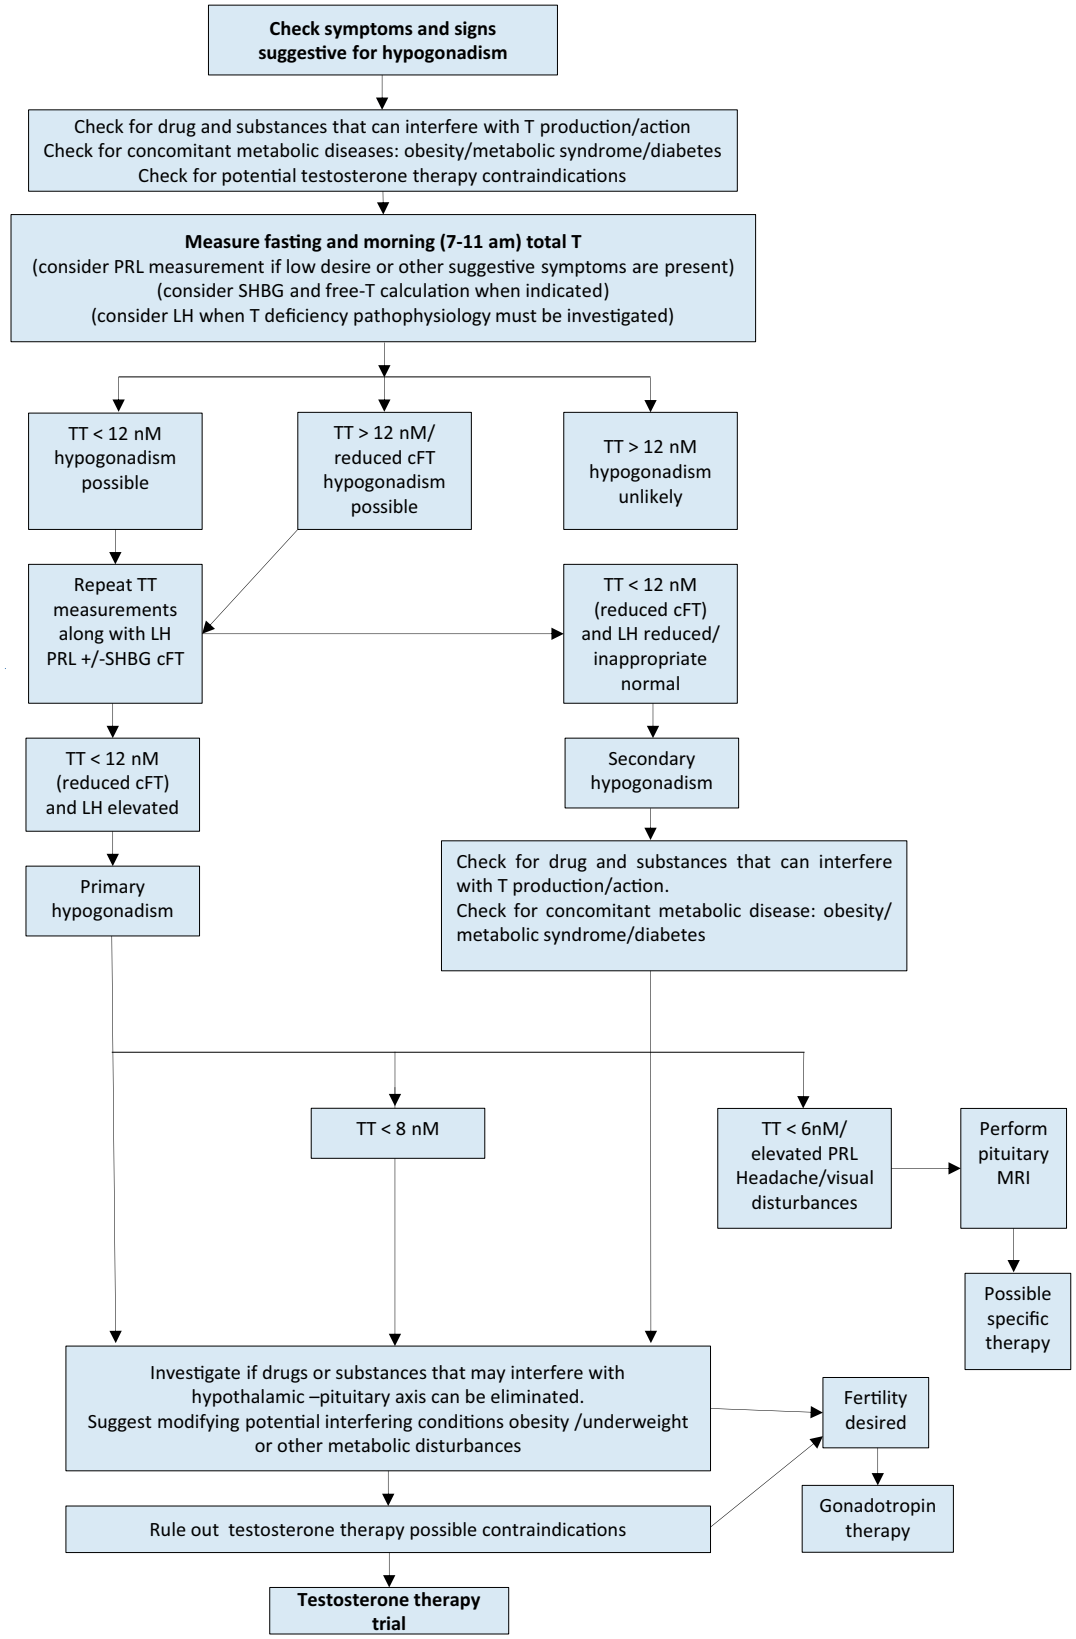
The mainstay of a LOH diagnosis includes the presence of signs and symptoms consistent with hypogonadism, coupled with biochemical evidence of low morning serum total testosterone levels on two or more occasions, measured with a reliable assay. Testosterone levels show a circadian variation, which persist in aging men [58, 59]. Likewise, testosterone levels are potentially influenced by food intake [60]; hence, serum total testosterone should be measured in fasting conditions and in the morning (between 7.00 and 11.00 hours). Moreover, a confirmatory measurement should always be undertaken in the case of a primary pathological value.

Liquid Chromatography-Tandem Mass Spectrometry (LC-MS/MS) represents the standard and most accurate method for sex steroid evaluation; however, standardised automated platform immuno-assays for total testosterone assessment demonstrate a good correlation with LC-MS/MS [61]. Conversely, available immuno-assays are not able to provide an accurate estimation of fT; therefore, direct fT evaluation with these methods is not recommended and should be avoided [39]. Liquid chromatography-tandem mass spectrometry remains the standard method for fT determination. Alternatively, fT can be derived from specific mathematical calculations taking into account serum SHBG and albumin levels [62] (http://www.issam.ch/freetesto.htm).

Data derived from available meta-analyses have documented that testosterone therapy is ineffective when baseline levels are above 12 nmol/L (3.5 ng/mL). Positive outcomes are documented when testosterone levels are below 12 nmol/l, being higher in symptomatic patients with more severe forms of hypogonadism (T < 8 nmol/L). Hence, 12 nmol/L should be considered as a possible cut-off to start with testosterone therapy in the presence of hypogonadal symptoms [21, 63]. As reported above, in the presence of clinical conditions which may potentially interfere with SHBG levels, the evaluation of fT should be considered in order to better estimate of androgen levels (Figure 2). Unfortunately, despite its potential clinical value [64], no validated thresholds for fT are available from clinical studies and this represents an area of uncertainty; however, some data indicate that fT levels below 225 pmol/L (< 6.5 ng/dl) are associated with hypogonadal symptoms [10, 49, 65, 66].

The determination of LH must be performed along with prolactin (PRL) when pathological total testosterone levels are detected, in order to correctly define the underlying conditions and exclude possible organic forms (Figure 2). Due to its negative influence on libido, PRL can be also be considered as first-line screening in patients with reduced sexual desire. In addition, pituitary magnetic resonance imaging (MRI) scanning, as well as other pituitary hormone evaluation, is required in the presence of specific symptoms such as visual disturbances, headache [67, 68] or when hyperprolactinaemia is confirmed. In addition, limited evidence suggests performing pituitary MRI also in the case of severe hypogonadism (< 6 nmol/L; 1.75 ng/mL) with inadequate gonadotropin levels (Figure 2) [67, 68].

Figure 2: Diagnostic evaluation of Late-Onset Hypogonadism



TT = total testosterone; cFT = calculated free testosterone; PRL = prolactin; SHBG = sex hormone-binding globulin; LH = luteinising hormone; MRI = Magnetic resonance imaging.

History taking

Specific symptoms associated with LOH are shown in Table 3. Past history of surgical intervention for cryptorchidism or hypospadias must be taken into account as possible signs of congenital defects. Likewise, chronic and systemic comorbid conditions must be comprehensively investigated in every patient. Possible use of drugs potentially interfering with the HPG axis should be ruled out (Table 2). Acute illnesses are associated with the development of functional hypogonadism and the determination of serum total testosterone levels should be avoided in these conditions. Several self-reported questionnaires or structural interviews have been developed for the screening of hypogonadism. Although these case-history tools have demonstrated clinical utility in supporting the biochemical diagnosis of hypogonadism, or in the assessment of testosterone therapy outcomes, their specificity remains relatively poor and they should not be used for a systematic screening of hypogonadal men [69].

Table 3: Specific symptoms associated with LOH

	Sexual symptoms	**Physical symptoms**	**Psychological symptoms**
More specific	- Reduced libido - Erectile dysfunction - Decreased spontaneous/ morning erections	- Decreased vigorous activity - Difficulty walking >1 km - Decreased bending	- Low mood/mood deflection - Decreased motivation - Fatigue
Less specific	- Reduced frequency of sexual intercourse - Reduced frequency of masturbation - Delayed ejaculation	- Hot flushes - Decreased energy - Decreased physical strength/function/activity	- Concentration or mnemonic difficulties - Sleep disturbances

*3.5.2 **Physical examination***

Since obesity is frequently associated with hypogonadism (mostly functional), the determination of body mass index (BMI) and the measurement of waist circumference are strongly recommended in all individuals. Testicular and penile size, as well the presence of sexual secondary characteristics can provide useful information regarding overall androgen status. In addition, upper segment/lower segment ratio (n.v. > 0.92) and arm-span to height ratio (n.v. < 1.00) can be useful to identify a eunochoid body shape, especially in subjects with pre-pubertal hypogonadism or delayed puberty. Finally, digital rectal examination (DRE) should be performed in all subjects to exclude prostate abnormalities before testosterone therapy (any type) or to support the suspicion of hypogonadism [70].

*3.5.3 **Summary of evidence and recommendations for the diagnostic evaluation of LOH***

Summary of evidence
Sexual symptoms are the most specific symptoms associated with LOH.
The diagnosis of LOH should be based on specific signs and symptoms of androgen deficiency, together with consistently low serum testosterone levels.
Functional hypogonadism is a consequence of comorbidities/concomitant drugs, which can impair testosterone production in adulthood. The diagnosis of functional hypogonadism is a diagnosis of exclusion, after ruling out organic causes of hypogonadism.

Recommendations	Strength rating
Check for concomitant diseases, drugs and substances that can interfere with testosterone production/action.	Strong
Total testosterone must be measured in the morning (7.00 and 11.00 hours) and in the fasting state, with a reliable method.	Strong
Repeat total testosterone on at least two separate occasions when below 12 nmol/L and before starting testosterone therapy.	Strong
12 nmol/L total testosterone (3.5 ng/mL) represents a reliable threshold to diagnose late onset hypogonadism (LOH).	Strong
Consider sex hormone-binding globulin and free-testosterone calculation when indicated.	Strong
Calculated free-testosterone < 225 pmol/L has been suggested as a possible cut off for diagnosis of LOH.	Weak
Analyse luteinising hormone and follicle-stimulating hormone serum levels to differentiate between primary hypogonadism and secondary hypogonadism forms.	Strong
Consider prolactin (PRL) measurement if low desire (or other suggestive signs/symptoms) and low or low-normal testosterone is present.	Strong
Perform pituitary magnetic resonance imaging (MRI) in secondary hypogonadism, with elevated PRL or specific symptoms of a pituitary mass and/or presence of other anterior pituitary hormone deficiencies.	Strong
Perform pituitary MRI in secondary severe hypogonadism (total testosterone < 6 nmol/L).	Weak

*3.5.4 **Recommendations for screening men with LOH***

Recommendations	Strength rating
Screen for late onset hypogonadism (including in T2DM) only in symptomatic men.	Strong
Do not use structured interviews and self-reported questionnaires for systematic screening for LOH as they have low specificity.	Strong

3.6 Treatment of LOH

*3.6.1 **Indications and contraindications for treatment of LOH***

Patients with symptomatic hypogonadism (total testosterone < 12 nmol/L) without specific contraindications are suitable candidates to receive testosterone therapy (Table 4).

Absolute contraindications are untreated breast and prostate cancer (PCa). Acute cardiovascular events as well as uncontrolled or poorly controlled congestive heart failure and severe low urinary tract symptoms (International Prostate Symptom Score (IPSS) score > 19) represent other relative contraindications, as there is not sufficient information on the long-term effects of testosterone therapy in these patients [66]. In addition, a positive familial history for venous thromboembolism requires further analyses in order to exclude a condition of undiagnosed thrombophilia-hypofibrinolysis [71]. These patients need to be carefully counselled prior to testosterone therapy initiation. A haematocrit (HCT) level higher than 54% should require testosterone therapy withdrawal, reduction in dose, change of formulation and venesection depending on the clinical situation in order to avoid any potential cardio-vascular complications. Lower levels of baseline HTC (48-50%) should be carefully evaluated before testosterone therapy initiation, in order to avoid pathological increases during treatment, especially in high-risk men such as those with chronic obstructive pulmonary disease (COPD) or Obstructive Sleep Apnea Syndrome (OSAS). Accordingly, the Framingham Heart Study showed that HTC > 48% represented a condition associated with an increased risk of coronary artery disease (CAD) and mortality and was associated with cardio-vascular disorders [72]. Finally, testosterone therapy suppresses gonadotropins and endogenous testosterone secretion as well as spermatogenesis. Hence, testosterone therapy is contraindicated in individuals who desire fertility [73]. Secondary hypogonadism is characterised by low or inappropriately normal gonadotropin levels; therefore, the rationale is to substitute the gonadotropin deficiency with FSH and LH analogues, if fertility is desired [74].

Table 4: Main contraindications of testosterone therapy

Absolute contraindications	Locally advanced or metastatic prostate cancer (PCa) Male breast cancer Men with an active desire to have children Haematocrit ≥ 54% Uncontrolled or poorly controlled congestive heart failure
Relative contraindication	IPSS score > 19 Baseline haematocrit 48-50% Familial history for venous thromboembolism

*3.6.2 **Testosterone therapy outcomes***

3.6.2.1 Sexual dysfunction

Sexual concerns are the main symptoms of the hypogonadal patient [5, 10, 75, 76]. A consistent body of evidence shows that testosterone therapy in hypogonadal men (total testosterone < 12 nmol/L) may have a beneficial effect on several aspects of sexual life; in contrast, there is no evidence of benefits in using testosterone for treating sexual dysfunction in eugonadal men [51, 63, 77, 78]. The beneficial effects on sexual function seems to be more related to testosterone level normalisation rather than the specific testosterone formulations used [78, 79].

A recent meta-analysis of only placebo controlled RCTs using the International Index of Erectile Function (IIEF) [80] as a possible tool for outcome evaluation, showed that testosterone therapy significantly improves erectile function (as measured by IIEF-Erectile Function domain score) and that patients with more severe hypogonadism (i.e., total testosterone < 8 nmol/L) are more likely to achieve a better improvement than patients with milder hypogonadism (i.e., total testosterone < 12 nmol/L). Similar results were observed for sexual desire; however, the presence of metabolic comorbidities (such as diabetes and obesity) decreased the magnitude of these improvements. In particular, testosterone therapy alone resulted in a clinically effective outcome only in patients with milder ED [63]. Other sexual function parameters, such as intercourse, orgasm and overall satisfaction, were all improved compared with placebo [63]. Men with comorbidities such as diabetes usually show modest improvements in terms of sexual function after testosterone therapy and may potentially require concomitant phosphodiesterase type 5 inhibitors (PDE5Is) to improve effectiveness [5, 78]. However, the specific beneficial effect derived from the combined use of testosterone therapy and PDE5Is is not completely clear [51]. Similarly, information related to the combined use of testosterone therapy with other ED pharmacotherapies is lacking [5, 78].

The Sexual Function Trial of the Testosterone Trials (one of the largest placebo-controlled trials on testosterone therapy) documented consistent improvements in ten of twelve measures of sexual activities in older (≥ 65 years old) hypogonadal men particularly in frequency of intercourse, masturbation and nocturnal erections (as measured by PDQ-Q4) [81]. The magnitude in improvement was shown to be proportional to the increase in serum total testosterone, fT and E2 levels, it was not possible to demonstrate a threshold level [82]. Furthermore, a study of 220 men with MetS with or without T2DM also found that sexual function did improve in those men who reported sexual problems with improvement in IIEF scores with specific increases in libido and sexual satisfaction [24].

3.6.2.2 Body composition and metabolic profile

Late onset hypogonadism is associated with a greater percentage fat mass and a lesser lean mass compared to testosterone replete men [83]. The major effect of low testosterone is to increase visceral adiposity but also leads to deposition of lipids in the liver and muscle and is associated with atherosclerosis [19]. As detailed above, a number of published data has suggested that testosterone therapy reduces percentage body fat and increases lean mass [84]. Moreover, testosterone therapy also has been also found to decrease waist circumference, body weight and BMI, with these effects more predominant after twelve months of treatment [84-86]. However, it should be recognised that these results are mainly derived from registry and observational trials which have important limitations due to the risk of selection bias for the non-random assignment of testosterone exposure. Accordingly, data derived from RCTs showed only an improvement of fat mass and lean mass of the same amount without any modifications in body weight [21].

3.6.2.3 Mood and cognition

Several observational studies have documented a relationship between depressive symptoms, reduced QoL and hypogonadism [87, 88]. However, the specific relationship between hypogonadism and the incidence of

depression is still unclear [88]. Only a few placebo-controlled RCTs have investigated the role of testosterone therapy in improving depressive symptoms. Data derived from TTrials showed that testosterone therapy improved mood, and depressive symptoms as continuous measures using several instruments [81]. However, the final effect was small in magnitude. In line with this data, the largest meta-analysis of available studies, including 1,890 hypogonadal (baseline total testosterone < 12 nmol/L or fT < 225 pmol/L) men from 27 RCTs, documented that the positive effect of testosterone therapy was particularly evident in patients with milder symptoms [89]. The BLAST study of testosterone therapy in T2DM reported that those men with depression were less likely to respond in regard to symptoms of sexual dysfunction compared to men without depression [29].

Robust data on the effect of testosterone therapy on QoL are limited. Although recent meta-analyses suggest a significant effect of testosterone therapy over placebo, the magnitude is low and the heterogeneity high, therefore reducing the scientific value of the effect [79, 90].

The role of testosterone therapy in patients with cognitive impairment is even more uncertain. The TTrials evaluated the effect of testosterone therapy in 493 individuals with age-associated memory impairment in order to assess possible improvement of several aspects of cognitive function. However, the final results failed to demonstrate any beneficial effect of testosterone therapy in improving cognitive function [81].

3.6.2.4 Bone

Evidence suggests that bone mineralisation requires circulating sex steroids within the normal range [91]. The possible association between mild hypogonadism and osteopenia/osteoporosis is weak, whereas severe hypogonadism (total testosterone < 3.5 nM) is frequently associated with bone loss and osteoporosis, independent of patient age [91]. Two independent meta-analyses showed a positive effect of testosterone therapy on bone mass density (BMD), with the highest effect at the lumber level [92, 93]. Similarly, data derived from TTrials confirmed that testosterone therapy increased BMD in hypogonadal aging men, particularly at the lumbar level [81]. However, available data is insufficient to determine the effect of testosterone therapy alone on the risk of bone fractures [91]. In addition, the use of testosterone therapy as an adjunct to anti-resorptive treatment in hypogonadal patients at high risk of fractures is not established. Therefore, anti-resorptive therapy alone must be the first-choice treatment in hypogonadal men at high risk for bone fractures. The combination of anti-reabsorptive treatment with testosterone therapy should be offered only in conjunction with hypogonadal related symptoms.

3.6.2.5 Vitality and physical strength

The role of testosterone in stimulating muscle growth and strength is well-established. Accordingly, androgenic-anabolic steroids (AAS) have been using as performance-enhancing agents for increasing physical performance in several competitive sport [94]. To this aim, testosterone therapy in hypogonadal men has been showed to both increase muscle mass and to reduce fat mass, with limited effects on final weight [21]. Despite this evidence, the role of testosterone therapy in older men with mobility limitations remains unclear. Findings from the National Health and Nutrition Examination Survey 1999-2004 [95] were unable to detect any association between overall circulating testosterone levels and the amount of physical activity. However, among non-obese men, those in the highest physical activity tertile were significantly less likely to have low or low normal testosterone than those in the lowest tertile. Data from TTrials indicated that testosterone therapy did not substantially increase the fraction of men whose distance walked in six minutes increased > 50 m or the absolute increase in the distance walked by the 387 subjects enrolled in the physical function trial [81]. However, when the whole population of the TTrials was considered, a significant, although modest, positive effect on these two parameters was reported [81]. Similar data were derived from the Vitality Trial [81].

3.6.2.6 Summary of evidence and recommendations for testosterone therapy outcome

Summary of evidence
Testosterone therapy can improve milder forms of ED and libido in hypogonadal men.
Testosterone therapy can improve other sexual symptoms, including intercourse frequency, orgasm and overall satisfaction.
Testosterone therapy can similarly increase lean mass, and reduce fat mass, and improves insulin resistance.
Testosterone therapy may improve weight, waist circumference and lipid profile, but findings are not unique.
Testosterone therapy can improve milder depressive symptoms in hypogonadal men.
Testosterone therapy can improve bone mineral density, but information related to fracture risk is lacking.

Recommendations	Strength rating
The use of testosterone therapy T in eugonadal men is not indicated.	Strong
Use testosterone therapy as first-line treatment in symptomatic hypogonadal patients with milder ED.	Strong
Use the combination of phosphodiesterase type 5 inhibitors and testosterone therapy in more severe forms of ED as it may result in better outcomes.	Weak
Use conventional medical therapies for treating severe depressive symptoms and osteoporosis.	Strong
Do not use testosterone therapy to improve body composition, reduce weight and benefit cardio-metabolic profile.	Weak
Do not use testosterone therapy for improving cognition vitality and physical strength in aging men.	Strong

*3.6.3 **Choice of treatment***

3.6.3.1 Lifestyle factors

As reported above, functional hypogonadism is frequently associated with obesity and metabolic disorders [96]. Therefore, weight loss and lifestyle changes should be the first approach for all overweight and obese men with hypogonadism. A previous meta-analysis documented that a low calorie diet is able to revert obesity-associated secondary hypogonadism by increasing total testosterone and fT, reducing oestrogens and restoring normal gonadotropin circulating levels [97]. This was confirmed in a recent updated meta-analysis showing that the increase in testosterone was significantly associated with weight reduction [98]. Similar results can be obtained through physical activity, which is associated with the duration of scheduled exercise and weight loss obtained [98]. However, it should be recognised that the increase in testosterone levels observed after a low calorie diet and physical activity is rather modest (1-2 nmol) [97, 98]. In addition, it should be recognised that from 60% to 86% of weight lost is regained after three years and 75% to 121% after five years [99]. A greater testosterone increase can be achieved through bariatric surgery, which results in an average increase of about 10 nmol/L depending on the degree of weight loss [98]. Lifestyle changes represent a relevant and essential part of the management of obesity; however, some evidence suggests that when compared to lifestyle modifications alone, in obese men, testosterone therapy-treated men benefited most from symptomatic relief of their symptoms associated with testosterone deficiency whereas those not treated did not [74]. Accordingly limited evidence suggests that the combination of life-style interventions and testosterone therapy in symptomatic hypogonadal men might result in better outcomes [83]. In particular, a large placebo-controlled RCT aimed to determine whether testosterone treatment combined with lifestyle intervention or lifestyle intervention alone might reduce T2DM incidence and improve glucose tolerance at two years is ongoing [100]. The results of this RCT will better clarify this point.

3.6.3.2 Medical preparations

Several testosterone formulations are available (Table 5). Direct comparisons among different testosterone products are still lacking. Candidates for testosterone therapy should be adequately informed about the possible risks and benefits of all available testosterone preparations. The final choice should be based on the clinical situation, testosterone formulations availability and patient needs and expectations [101].

3.6.3.2.1 Oral formulations

The esterification of testosterone with a long-chain fatty acid (testosterone undecanoate; TU) enables testosterone to be absorbed by the intestine through the lymphatic system, by-passing liver metabolism. This formulation has been available in oleic acid since the 1970s, and it has been recently reformulated in a mixture of castor oil and propylene glycol laureate (TU caps), to allow the drug to be maintained at room temperature without any degradation of the product [102]. The main limitation is related to the poor bioavailability, which is strongly dependent on the dietary fat content [102]. Recently, the US Food and Drug Administration (FDA) approved a new formulation of oral TU incorporating a liquid-filled hard capsule drug delivery system and containing a higher amount (225 mg) of the compound, which improves oral availability (https://www.fda.gov/media/110187/download). In an open label study of approximately four months duration (NCT02722278), 145 (87%) of 166 hypogonadal men enrolled who received the TU caps formulation had mean total testosterone concentration within the normal eugonadal range at the end of treatment (https://www.fda.gov/media/110187/download). However, the TU caps compound is not available in Europe.

Mesterolone is a 5α-DHT derivate available for oral administration. Along with DHT, it cannot be converted to oestrogens and can be used for a limited period and specific indications, such as the presence of painful gynecomastia. However, the lack of a full spectrum of testosterone bioactivity strongly limits its long-term use [102].

3.6.3.2.2 Parenteral formulations

Injectable testosterone preparations can be classified according to their half-lives (Table 5). Testosterone propionate is a short-term ester formulation requiring multiple fractionated doses (usually 50 mg, every two to three days), thus representing a major limitation for its use [102]. Cypionate and enanthate-T esters are short-term formulations, requiring administration every two to four weeks. A formulation containing mixed testosterone esters (TU, isocaproate, phenyl propionate, propionate - Sustanon®) which allows some benefit of a smoother release of testosterone into the circulation is available in some countries. The use of these older formulations is associated with wide fluctuations in plasma testosterone concentrations, often reported as unpleasant by patients and potentially resulting in side effects, such as polycythemia [102, 103]. A longer lasting TU injectable formulation is widely available [102]; this formulation has been demonstrated to have a very good safety/benefit profile allowing the maintenance of normal stable testosterone levels with a dosing regimen of 1,000 mg initially every twelve weeks, following a six-week loading dose, but can be adjusted to a frequency of ten to fourteen weeks dependent on the trough (pre-injection level) after three to five injections to maintain levels in the therapeutic range (usually >12nmo/L and less than 18nmol/L at that time point [102, 104].

3.6.3.2.3 Transdermal testosterone preparations

Among the available transdermal formulations, testosterone gels represent the most frequently used preparations. The gel is quickly absorbed by the stratum corneum, creating a reservoir within the subcutaneous tissues from where testosterone is continuously delivered for 24 hours, after a single daily application. These formulations have been shown to normalise serum testosterone levels with an excellent safety profile [102]. In addition, the introduction of specific devices and skin enhancers has resulted in better skin penetration of the drugs, thus reducing potential side effects. Adverse local skin side effects are limited when compared to testosterone patches, but they potentially allow transference of testosterone during close contact with the skin's surface. The risk can be reduced by wearing clothing or by applying the gel on skin surfaces not usually touched (e.g., the inner thigh surface) [102]. Moreover, in order to reduce the total amount of gel applied and residual quantities remaining on the skin, new formulations of testosterone gel have been introduced with a testosterone concentration of 1.62-2% [102]. Another transdermal testosterone formulation includes a topical, alcohol-based testosterone (2%) solution, which must be applied to the underarm once daily, using a metered dose applicator [102]. This testosterone formulation is not available in Europe. Testosterone levels should be monitored to optimise the testosterone dose. Blood collection is best taken between 2-4 hours after gel application to use the peak level of testosterone absorbed as a reference for adequate therapeutic levels. Levels of testosterone after application can vary and a repeat measurement may be indicated especially as sometimes inadvertently the skin over the site of the vene-puncture can be contaminated by the gel leading to falsely elevated results.

In some European countries, DHT is available as a hydroalcoholic 2.5% gel. It is rapidly absorbed, reaching a steady state in 2-3 days. Similar to what reported for mesterolone, DHT is not aromatised but can be useful for treating particular conditions, such as gynecomastia and microphallus [102].

3.6.3.2.4 Transmucosal formulations

3.6.3.2.4.1 Transbuccal Testosterone preparations

A testosterone buccal system is still available in several countries. It consists on a sustained-release muco-adhesive buccal-testosterone-tablet requiring twice-daily application to the upper gums. The tablet does not dissolve completely in the mouth and must be removed after twelve hours. This formulation has been proven to restore testosterone levels within the physiological range with minimal or transient local problems, including gum edema, blistering and gingivitis [102].

3.6.3.2.4.2 Transnasal testosterone preparations

A gel for intranasal administration is available in some countries, including the USA and Canada. It requires administration two or three times a day using a specific metered-dose pump. The application is rapid, non-invasive, convenient, and avoids secondary transference observed with other topical products [102].

3.6.3.2.5 Subdermal depots

The implantation of testosterone pellets, available in the USA, UK and Australia, represents the longest available testosterone formulation lasting from four to seven months. However, the procedure is invasive and may be unattractive to patients [102].

3.6.3.2.6 Anti-oestrogens

Anti-oestrogens, including selective oestrogen receptor (ER) modulators (SERMs) and aromatase inhibitors (AI) have been suggested as "off-label" treatments to restore testosterone levels and fertility in men with functional secondary hypogonadism or idiopathic infertility. Essentially, they work by preventing down-regulation of the

HPG axis by oestrogens and, for this reason are particularly useful in men with obesity and metabolic disorders [98]. In the latter case, the hypothesis is that the excess of adipose tissue leads to increased aromatase activity and oestrogens levels resulting in impairment of HPG [96]. Due to their putative mechanism of action, they require an intact HPG axis and cannot work in primary hypogonadism or secondary hypogonadism due to organic damage of the HPG axis. Both SERMs, which bind ERs with an agonist or antagonist effect depending upon the target tissue, and AIs, which prevent androgens from being converted into oestrogens by aromatase, have been used in clinical practice [102]. The evidence published so far is poor; all these products are off-label treatments and SERMs, due to their agonistic effect on venous vessels, could predispose men to the development of venous thromboembolic disease [102]. In this context patients should be warned of the potential increased risk of venous thromboembolic disorders although data is lacking. Long-term use of these agents can lead to reduced bone density and the development of osteoporosis potentially increasing fracture risk.

3.6.3.2.7 Gonadotropins

Considering the aforementioned limitations regarding the use of anti-oestrogens, gonadotropin therapy should be considered the standard treatment in men with secondary hypogonadism who desire paternity (Table 5) [102]. The treatment is based on the use of human chorionic gonadotropin (hCG), purified from the urine of pregnant women. The most expensive recombinant hCG (rhCG) and LH (rhLH) formulations do not offer clinical advantages [102]. According to a meta-analysis of the available evidence, the use of hCG should be administered with FSH as the combined therapy results in better outcomes. Similar to hCG, the use of recombinant FSH (rFSH) does not seem not to offer any advantages compared to urinary-derived preparations [105]. More details on the use of gonadotropins is provided in section 9.

Table 5: Available preparations for hypogonadism treatment

Formulation	Chemical structure	T 1/2	Standard dosage	Advantages	Disadvantages
GONADOTROPINS					
Human chorionic gonadotrophin (HCG)					
Extractive	HCG purified from the urine of pregnant women	NA	1,000 - 2,000 IU 3 times/ week	Low cost	Multiple weekly administration
Recombinant	Human recombinant HCG	NA	No data in men	NA	
Luteotropic hormone (LH)					
Recombinant	Human recombinant LH	NA	No data in men	NA	
Follicle-stimulating hormone (FSH)					
Extractive	FSH purified from the urine of pregnant women	NA	75-150 IU 3 times/week	High cost	Multiple weekly administration
Recombinant	Human recombinant FSH	NA	75-150 IU 3 times/week	High cost	Multiple weekly administration
TESTOSTERONE PREPARATIONS					
Oral					
Testosterone undecanoate	17-α-hydroxylester	4 hours	120-240 mg 2-3 times daily	- Reduction of liver involvement - Oral convenience - Modifiable dosage	- Unpredictable absorption depending of meal fat content - Has to be taken with meals
Mesterolone	1α-methyl-4, 5α-dihydro-testosterone	12 hours	50-100 mg 2-3 times daily	- Oral convenience - Modifiable dosage - Useful in gynecomastia	- Not aromatisable

Parental					
Testosterone enanthate	17-α-hydroxylester	4-5 days	250 mg every 2-3 weeks	- Low cost - Short-acting preparation allowing drug withdrawal in case of side-effects	- Fluctuations in circulating testosterone levels - Multiple injections - Relative risk of polycythemia
Testosterone cypionathe	17-α-hydroxylester	8 days	200 mg every 2-3 weeks	- Low cost - Short-acting preparation allowing drug withdrawal in case of side-effects	- Fluctuations in circulating testosterone levels - Multiple injections - Relative risk of polycythemia
Testosterone propionate	17-α-hydroxylester	20 hours	100 mg every 2 days	- Low cost - Very short-acting preparation allowing drug withdrawal in case of side-effects	- Fluctuations in circulating testosterone levels - Multiple injections - Relative risk of polycythemia
Testosterone ester mixture Propionate (30mg) Phenylpropionate (60 mg) Isocaproate (60 mg) Decanoate (100 mg)	4-androsten-3-one-17 beta-hydroxy-androst-4-en-3-one	4-5 days	250 mg every 3 weeks	- Low cost - Short-acting preparation allowing drug withdrawal in case of side-effects	- Fluctuations in circulating testosterone levels - Multiple injections - Relative risk of polycythemia
Testosterone undecanoate in castor oil	17-α-hydroxylester	34 days	1000 mg every 10-14 weeks *750 mg every 10 weeks	- Steady-state testosterone level without fluctuation - Long-lasting - Less frequent administration	- Pain at injection site - Long-acting preparation not allowing rapid drug withdrawal in case of side-effects
Surgical implants	Native testosterone	--	4-6 200 mg implants lasting up to 6 months	- Long duration and constant serum testosterone level	- Placement is invasive - Risk of extrusion and site infections
TRANSDERMAL					
Testosterone patches	Native testosterone	10 hours	50-100 mg/ day	Steady-state testosterone level without fluctuation	- Skin irritation - Daily administration
Testosterone gel 1-2%	Native testosterone	6 hours	50-100 mg/ day	Steady-state testosterone level without fluctuation	- Possible transfer during intimate contact - Daily administration
Underarm testosterone (testosterone solution 2%)	Native testosterone	NA	60-120 mg/ day	Steady-state testosterone level without fluctuation	- Possible transfer during intimate contact - Daily administration
Dihydro-testosterone gel 2.5%	Native dihydro-testosterone	NA	34-70 mg/day	- Steady-state testosterone level without fluctuation - Useful in gynecomastia	- Possible transfer during intimate contact - Daily administration - Not aromatisable

TRANSMUCOSAL					
Testosterone buccal system	Native testosterone	12 hours	60 mg 3 times daily	Steady-state testosterone level without fluctuation	- Possible oral irritation - Twice-daily dosing - Unpleasant taste
Testosterone nasal	Native testosterone	6 hours	33 mg 3 times daily	Steady-state testosterone level without fluctuation	- Nasal irritation - Multiple daily administration

NA = not applicable.

3.6.3.3 Summary of evidence and recommendations for LOH choice of treatment

Summary of evidence
Weight loss obtained through a low calorie diet and physical activity result in a small improvement in testosterone levels.
Testosterone gels and long-acting injectable TU represent testosterone preparations with the best safety profile.
Gonadotropin treatment can be used to restore fertility in men with secondary hypogonadism.

NA = not applicable.

Recommendations	**Strength rating**
Treat, when indicated, organic causes of hypogonadism (e.g., pituitary masses, hyperprolactinaemia, etc).	Strong
Improve lifestyle and reduce weight (e.g., obesity); withdraw, when possible, concomitant drugs which can impair testosterone production; treat comorbidities before starting testosterone therapy.	Weak
Fully inform the patient about expected benefits and side effects of any treatment option. Select the testosterone preparation in a joint decision process, only with a fully informed patient.	Strong
The aim of testosterone therapy is to restore serum testosterone concentration to the average normal range for young men.	Weak
Use testosterone gels rather than long-acting depot administration when starting initial treatment, so that therapy can be adjusted or stopped in the case of treatment-related adverse side effects.	Weak

3.7 Safety and follow up in hypogonadism management

*3.7.1 **Hypogonadism and fertility issues***

The aim of the pharmacological management of hypogonadism is to increase testosterone levels. The first choice is to administer exogenous testosterone. However, while exogenous testosterone provides benefits to the clinical symptoms of hypogonadism, it also inhibits gonadotropin secretion by the pituitary gland, resulting in impaired spermatogenesis and sperm cell maturation [106]. Therefore testosterone therapy is contraindicated in hypogonadal men seeking fertility treatment [73]. When secondary hypogonadism is present, gonadotropin therapy can maintain normal testosterone levels and restore sperm production [5].

*3.7.2 **Male breast cancer***

In vitro and *in vivo* studies have clearly documented that breast cancer growth is significantly influenced by testosterone and/or by its conversion to E2 through different mechanisms and pathways [107]. Accordingly, the use of SERMs still represents an important therapeutic option in the management of this cancer [107]. No information is available on the role of testosterone therapy in patients successfully-treated for male breast cancer; therefore, treated and active male breast cancer should be recognised as absolute contraindications for testosterone therapy.

3.7.3 Lower urinary tract symptoms/benign prostatic hyperplasia

Based on the assumption that prostate growth is dependent on the presence of androgens, historically testosterone therapy has raised some concerns regarding the possibility of aggravating lower urinary tract symptoms (LUTS) in patients affected by benign prostatic hyperplasia (BPH) [70, 108]. However, pre-clinical and clinical data has indicated that low rather than higher androgen levels may decrease bladder capacity, alter tissue histology and decrease the ratio of smooth muscle to connective tissue, impairing urinary dynamics [70, 108].

A trial of 60 patients undergoing testosterone therapy for six months showed no significant differences in post-voidal residual urine and prostate volume, while storage symptoms as measured by the IPSS significantly improved, despite an increase in PSA level. A larger pre-treatment prostate volume was a predictive factor of improvement in LUTS [109]. A long-term study of 428 men undergoing testosterone therapy for eight years demonstrated significant improvements in IPSS score, no changes in Q_{max} and residual urine volume, but also a significant increase in prostate volume [110]. Similarly data from the Registry of Hypogonadism in Men (RHYME), including 999 subjects with a follow-up of three years, did not document any difference in prostate-specific antigen (PSA) levels, total IPSS score in men undergoing testosterone therapy, compared to those untreated [111]. Similar results were reported in an Italian registry (SIAMO-NOI), collecting data from 432 hypogonadal men from fifteen centres [112]. Accordingly, available meta-analyses did not find significant changes in LUTS compared to placebo [113-119]. On the basis of the most recent literature, there are no grounds to discourage testosterone therapy in hypogonadal patients with BPH/LUTS; instead there is evidence of limited benefit from androgen administration. The only concern is related to patients with severe LUTS (IPSS score >19), as these patients are usually excluded from RCTs, therefore limiting the long-term safety data of testosterone therapy in these subjects [70].

*3.7.4 **Prostate cancer (PCa)***

A considerable number of observational studies have failed to demonstrate any association between circulating higher testosterone levels and PCa [120]. On the other hand, analytical studies aimed at investigating the relationship between low levels of testosterone and the risk of PCa have found that men with very low levels of fT have a reduced risk of developing low-to-intermediate grade PCa, but have a non-significantly increased chance of developing high grade disease [120]. This peculiar pattern was also reported in previous trials such as the Health Professionals Follow-up Study, the PCPT and by the Reduction by Dutasteride of Prostate Cancer Events (REDUCE), with varying magnitudes of significance [121].

The most recent meta-analysis, including 27 placebo-controlled, RCTs found no evidence of increased PSA levels following testosterone therapy for one year. When considering eleven studies reporting on the occurrence of PCa, the meta-analysis found no evidence of an increased risk of PCa. However, a one-year follow-up may be considered too short a time to draw conclusions on PCa occurrence. Furthermore, the analysis was also restricted to studies with longer than one-year follow-up, but no significant changes in PSA levels nor increased risk of PCa were found [114]. Furthermore, at five-year median follow-up in three independent registry studies with more than 1,000 patients undergoing testosterone therapy, PCa occurrence remained at all times well below the reported incidence rate in the general population [122]. Similar results were reported by a more recent large observational study including 10,311 men treated with testosterone therapy and 28,029 controls with a median follow-up of 5.3 years [123]. In addition, the same study, also showed that the risk of PCa was decreased for those subjects in the highest tertile of testosterone therapy cumulative dose exposure compared with controls [123].

With regards to PCa survivors, safety in terms of the risk of recurrence and progression has not yet been established. Limited data are available in the literature, with most case series not providing sufficient data to draw definitive conclusions (e.g. insufficient follow-up length, small sample sizes, lack of control arms, heterogeneity in study population and treatment regimen, etc.) [124]. More recently, a meta-analysis derived from thirteen studies including 608 patients, of which 109 had a history of high-risk PCa, with a follow-up ranging from one to 189.3 months [125] suggested that testosterone therapy did not increase the risk of biochemical recurrence, but the available evidence is very poor, limiting data interpretation [125]. Similar considerations can be derived from another meta-analysis including a larger number of studies (n=21) [126]. It is important to recognise that the vast majority of studies analysed, included low-risk patients with Gleason score < 8 [125].

In conclusion, recent literature does not support an increased risk of PCa in hypogonadal men undergoing testosterone therapy. On the other hand, while it is obviously necessary to avoid testosterone administration in men with advanced PCa, insufficient long-term prospective data on the safety of androgen administration in PCa survivors [126], without disease recurrence should prompt caution in choosing to treat symptomatic hypogonadal men in this setting. Specifically, patients should be fully counselled that the long-term effects of testosterone therapy in this setting are still unknown and requires further investigation. If the presence of an occult PCa is not detected before initiation of testosterone therapy, treatment may unmask the cancer detected by an early rise in PSA over six to nine months of therapy. Due to the lack of strong evidence-based data on safety, the possible use of testosterone therapy in symptomatic hypogonadal men previously treated for PCa should be adequately discussed with the patients and limited to low-risk subjects.

*3.7.5 **Cardiovascular Disease***

Evidence suggests that hypogonadal men have an increased risk of CVD [127, 128]. Whether or not LOH is a cause or consequence of atherosclerosis has not been clearly determined. Late-onset hypogonadism

is associated with CV risk factors which include central obesity, insulin resistance and hyperglycaemia, dyslipidaemia (elevated total cholesterol, LDL-cholesterol, triglycerides and low HDL-cholesterol), pro-thrombotic tendency and a chronic inflammatory state [129]. Atherosclerosis itself is a chronic inflammatory disease, which releases pro-inflammatory cytokines into the circulation which are known to suppress testosterone release from the HPG axis. Evidence from RCTs using testosterone therapy in men with MetS and/or T2DM have demonstrated some benefit in CV risk including a reduction in central adiposity, insulin resistance, total and LDL-cholesterol and suppression of circulating cytokines [14, 23-25, 29, 129]. However, due to the equivocal nature of these studies, testosterone therapy cannot be recommended for indications outside the specific symptoms.

Published data show that LOH is associated with an increase in all-cause and CVD-related mortality [12, 130-133]. These studies are supported by a meta-analysis which concluded that hypogonadism is a risk factor for cardiovascular mortality [134] and morbidity [118]. Importantly, men with low testosterone when compared to eugonadal men with angiographically proven coronary disease have twice the risk of earlier death [128]. Longitudinal population studies have reported that men with testosterone in the upper quartile of the normal range have a reduced number of CV events compared to the combined data from the lower three quartiles [130]. Androgen deprivation therapy for PCa is linked to an increased risk of CV events and sudden death [135]. Conversely, two long-term epidemiological studies reported reduced cardiovascular events in men with high normal serum testosterone levels [136, 137]. Erectile dysfunction is independently associated with CVD and may be the first clinical presentation of a male with atherosclerosis.

The knowledge that men with hypogonadism and/or ED may have underlying CVD should prompt an individual assessment of their CV risk profile. Individual risk factors (e.g. lifestyle, diet, exercise, smoking, hypertension, diabetes, dyslipidaemia) should be assessed and treated in men with pre-existing CVD and in patients treated with androgen deprivation therapy. Cardiovascular risk reduction can be managed by primary care clinicians, but they should be appropriately counseled by clinicians active in prescribing testosterone therapy [75]. If appropriate, they could be referred to cardiologist for risk stratification and treatment of co-existent comorbidities.

There are no RCTs that provide a clear answer, on whether testosterone therapy affects cardiovascular outcomes. The Ttrial (n=790) a study in older men [138], the TIMES2 (n=220) [24] and the BLAST studies in men with MetS and T2DM and the pre-frail and frail study in elderly men - all of one-year duration - did not reveal any increase in Major Adverse Cardiovascular Events (MACE) [24, 27, 138, 139]. In this context, MACE is defined as the composite of cardiovascular death, non-fatal acute myocardial infarction, acute coronary syndromes, stroke and cardiac failure. Randomised controlled trials between three and twelve months in men with known heart disease treated with testosterone have not found an increase in MACE events but did report improvement in cardiac ischaemia, angina and functional exercise capacity [140-142]. The European Medicines Agency (EMA) has stated 'The Co-ordination Group for Mutual recognition and Decentralisation Procedures-Human (CMDh), a regulatory body representing EU Member States, has agreed by consensus that there is no consistent evidence of an increased risk of heart problems with testosterone in men who lack the hormone (a condition known as hypogonadism). However, the product information is to be updated in line with the most current available evidence on safety, and with warnings that the lack of testosterone should be confirmed by signs and symptoms and laboratory tests before treating men with these medicines.' [143].

As a whole, as for MACE, current available data from interventional studies suggest that there is no increased risk with testosterone therapy with up to three-years of therapy [144-147]. The weight of the currently available published evidence has reported that testosterone therapy in men with diagnosed hypogonadism has neutral or beneficial actions on MACE in patients where the testosterone levels have been normalised. However, these findings could be considered sufficiently reliable for a three-year course of testosterone therapy, after which no available study may exclude further or long-term CV events [148, 149].

3.7.5.1 Cardiac Failure

Testosterone treatment is contraindicated in men with severe chronic cardiac failure because fluid retention may lead to an exacerbation of the condition. Some studies including one of twelve month's duration have shown that men with moderate chronic cardiac failure may benefit from low doses of testosterone, which achieve mid-normal range testosterone levels [141, 150, 151]. If a decision is made to treat hypogonadism in men with chronic cardiac failure, it is essential that the patient is followed up carefully with clinical assessment and both testosterone and haematocrit measurements on a regular basis. An interesting observation is that untreated hypogonadism increased the re-admission and mortality rate in men with heart failure [152].

3.7.6 ***Erythrocytosis***

An elevated haematocrit is the most common side effect of testosterone therapy. Stimulation of erythropoiesis is a normal biological action, which enhances the delivery of oxygen to testosterone sensitive tissues (e.g. striated, smooth and cardiac muscle). Any elevation above the normal range for haematocrit usually becomes evident between three and twelve months after testosterone therapy initiation. However, polycythaemia can also occur after any subsequent increase in testosterone dose, switching mode of formulation from topical to parenteral administration and if there is the development of a comorbidity, which can be linked to an increase in haematocrit (e.g. respiratory or haematological diseases).

There is no evidence that an increase of haematocrit up to and including 54% causes any adverse effects on health. If the haematocrit exceeds 54% there is a testosterone independent, but weak associated rise in CV events and mortality [72, 153-155]. Any relationship is complex as these studies were based on subjects with any cause of secondary polycythaemia, which included smoking and respiratory diseases. There have been no specific studies including men with only testosterone-induced erythrocytosis.

Three large studies have not shown any evidence that testosterone therapy is associated with an increased risk of venous thromboembolism [156, 157]. However, one study showed that an increased risk was observed peaking at six months after initiation of testosterone therapy, then declining over the subsequent period [158]. No study reported whether or not there was monitoring of the haematocrit, testosterone and/or E2 levels. High endogenous testosterone or E2 levels have not been associated with a greater risk of venous thromboembolism [159]. In one study venous thromboembolism was reported in 42 cases and 40 of these had a diagnosis of an underlying disorder of thrombophilia (including Factor V Leiden deficiency, prothrombin mutations, homocysteinuria) [160]. In an RCT of testosterone therapy in men with chronic stable angina there was no adverse effects on coagulation, by assessment of tissue plasminogen activator or plasminogen activator inhibitor-1 enzyme activity or fibrinogen levels [161]. A meta-analysis of RCTs of testosterone therapy reported that cases of venous thromboembolism were frequently related to underlying undiagnosed thrombophilia-hypofibrinolysis disorders [71].

With testosterone therapy an elevated haematocrit is more likely to occur if the baseline level is toward the upper limit of normal prior to initiation of therapy. Added risks for a raised haematocrit on testosterone therapy include factors, such as smoking or respiratory conditions at baseline. Higher haematocrit values are more common on parenteral rather than topical formulations. In men with pre-existing CVD extra caution is advised with a definitive diagnosis of hypogonadism before initiating testosterone therapy and monitoring of testosterone as well as the haematocrit over treatment.

An elevated haematocrit in the absence of any co-morbidities or acute cardiovascular or venous thromboembolism can be managed by a reduction in testosterone dose, change in formulation or if the elevated haematocrit is very high by venesection (500 mL) and repeated if necessary, with usually no need to stop the testosterone therapy.

3.7.7 ***Obstructive Sleep Apnoea***

There is also no evidence that testosterone therapy can result in the onset or worsening of sleep apnoea. It has been demonstrated that combined therapy with Continuous Positive Airway Pressure (CPAP) with the addition of testosterone gel was more effective than CPAP alone in the treatment of obstructive sleep apnoea [162]. In one RCT, testosterone therapy in men with severe sleep apnoea reported a reduction in oxygen saturation index and nocturnal hypoxaemia after seven weeks of therapy compared to placebo, but this change was not evident after eighteen weeks' treatment and there was no association with baseline testosterone levels [163].

3.7.8 ***Follow up***

Testosterone replacement therapy in hypogonadal men has proven to be effective in alleviating symptoms and signs in a specific time-dependent manner. The TTrials clearly showed that testosterone therapy may result in improvement of sexual symptoms as early as three months after testosterone therapy initiation [81]. Similar results have been derived from available meta-analyses [51, 71]. Hence, the first evaluation should be planned after three months of treatment. Further evaluation may be scheduled at six months or twelve months, according to patient characteristics, as well as results of biochemical testing (see below). Table 6 summarises the clinical and biochemical parameters that should be monitored during testosterone therapy.

Trials were designed to maintain the serum testosterone concentration within the normal range for young men (280-873 ng/dL or 9.6-30 nmol/L [81]. This approach resulted in a good benefit/risk ratio. Accordingly, a similar approach could be considered during follow-up. The correct timing for testosterone levels evaluation can vary according to the type of testosterone preparation used (Table 5). Testosterone is involved in the regulation of

erythropoiesis [103] and prostate growth [70], hence evaluation of PSA and haematocrit should be mandatory before and during testosterone therapy. However, it is important to recognise that the risk of PCa in men aged < 40 years in very low. Similarly, the risk of dying for PCa in men older than 70 years has not been considered high enough to warrant monitoring in the general population [164]. Hence, the screening for PCa through the determination of PSA and DRE in men younger than 40 older than 70 years during testosterone therapy should be discussed with the patients.

Baseline and, at least, annually glyco-metabolic profile evaluation may be a reasonable consideration, particularly in the management of functional hypogonadism. Moreover, since testosterone therapy may be beneficial for hypogonadal men with low or moderate fracture risk [91], dual energy X-ray absorptiometry (DEXA) bone scan may be also considered at baseline and 18-24 months following testosterone therapy, particularly in those subjects with more severe hypogonadism [91].

Digital rectal examination may detect prostate abnormalities, which can be present even in men with normal PSA values. Hence DRE is mandatory in all men at baseline and during testosterone therapy justify. The decision to stop testosterone therapy or to perform prostate biopsy due to PSA increase or prostate abnormalities should be based on local PCa guidelines. There is a large consensus that any increase of haematocrit > 54% over testosterone therapy requires testosterone therapy withdrawal and phlebotomy in order to avoid potential side effects including venous-thromboembolism and CV events especially in high-risk subjects. In patients with lower risk the situation can be alternatively managed by reducing testosterone dose and by switching formulation along with venesection. A positive family history of venous-thromboembolism should be carefully investigated and the patient counselled in regard to testosterone therapy in order to avoid/ prevent a condition of thrombophilia-hypofibrinolysis [71]. Finally, caution should be used in men with pre-existing CVD or at higher risk of CVD

Table 6: The clinical and biochemical parameters to be checked during testosterone therapy

Parameters	**1st year of treatment**	**After the first year of treatment**

*3.7.9 **Summary of evidence and recommendations on risk factors in testosterone treatment***

Summary of evidence
Testosterone therapy is contraindicated in men with secondary hypogonadism who desire fertility.
Testosterone therapy is contraindicated in men with active prostate or breast cancer.
Testosterone therapy does not increase the risk of prostate cancer, but long-term prospective follow-up data is required to validate this statement.
The effect of testosterone therapy in men with severe lower urinary tract symptoms is limited, as these patients are usually excluded from RCTs.
There is no substantive evidence that testosterone therapy, when replaced to normal levels results in the development of major adverse cardiovascular events.
There is no evidence of a relationship between testosterone therapy and mild, moderate or CPAP- treated severe sleep apnoea.

Recommendations	Strength rating
Fully counsel symptomatic hypogonadal men who have been surgically treated for localised prostate cancer (PCa) and who are currently without evidence of active disease considering testosterone therapy, emphasising the benefits and lack of sufficient safety data on long-term follow-up.	Weak
Restrict treatment to patients with a low risk for recurrent PCa (i.e., Gleason score < 8; pathological stage T1-2; pre-operative PSA < 10 ng/mL) and should start after at least one year follow-up with a PSA level < 0.01 ng/mL.	Weak
Safety data on the use of testosterone therapy in men treated for breast cancer are unknown.	Strong
Assess for cardiovascular risk factors before commencing testosterone therapy.	Strong
Assess men with known cardiovascular disease (CVD) for cardiovascular symptoms before testosterone therapy and with close clinical assessment and evaluation during treatment.	Strong
Treat men with hypogonadism and pre-existing CVD, venous-thromboembolism or chronic cardiac failure, who require testosterone therapy with caution, by careful clinical monitoring and regular measurement of haematocrit (not exceeding 54%) and testosterone levels.	Weak
Exclude a family history of venous-thromboembolism before commencing testosterone therapy.	Strong
Monitor testosterone, haematocrit at three, six and twelve months after testosterone therapy initiation, and thereafter annually. A haematocrit more than 54% should require testosterone therapy withdrawal and phlebotomy. Reintroduce testosterone therapy at a lower dose once the haematocrit has normalised and consider switching to topical testosterone preparations.	Strong

4. EPIDEMIOLOGY AND PREVALENCE OF SEXUAL DYSFUNCTION AND DISORDERS OF MALE REPRODUCTIVE HEALTH

4.1 Erectile dysfunction

Epidemiological data have shown a high prevalence and incidence of ED worldwide [165]. Among others, the Massachusetts Male Aging Study (MMAS) [166] reported an overall prevalence of 52% ED in non-institutionalised men aged 40-70 years in the Boston area; specific prevalence for minimal, moderate, and complete ED was 17.2%, 25.2%, and 9.6%, respectively. In the Cologne study of men aged 30-80 years, the prevalence of ED was 19.2%, with a steep age-related increase from 2.3% to 53.4% [167]. The incidence rate of ED (new cases per 1,000 men annually) was 26 in the long-term data from the MMAS study [168] and 19.2 (mean follow-up of 4.2 years) in a Dutch study [169]. In a cross-sectional real-life study among men seeking first medical help for new-onset ED, one in four patients was younger than 40 years, with almost 50% of the young men complaining of severe ED [170]. Differences between these studies can be explained by differences in methodology, in the ages, and socio-economic and cultural status of the populations studied. The prevalence rates of ED studies are reported in Table 7.

4.2 Premature ejaculation

As evidenced by the highly discrepant prevalence rates reported in Table 8 [171], the method of recruitment for study participation, method of data collection and operational criteria can all greatly affect reported prevalence rates of premature ejaculation (PE). The major problem in assessing the prevalence of PE is the lack of a universally recognised definition at the time the surveys were conducted [172]. Vague definitions without specific operational criteria, different manners of sampling, and non-standardised data acquisition have led to tremendous heterogeneity in estimated prevalence [172-176]. The highest prevalence rate of 31% (men aged 18-59 years) was found by the National Health and Social Life Survey (NHSLS) study, which determines adult sexual behavior in the United States [177]. Prevalence rates were 30% (18-29 years), 32% (30-39 years), 28% (40-49 years) and 55% (50-59 years). It is, however, unlikely that the PE prevalence is as high as 20-30% based on the relatively low number of men who present seeking medical help for PE. These high prevalence rates may be a result of the dichotomous scale (yes/no) in a single question asking if ejaculation occurred too early, as the prevalence rates in European studies have been significantly lower [178]. Two separate observational, cross-sectional surveys from different continents found the overall prevalence of the complaint of PE to be

19.8 and 25.80%, respectively [179, 180]. Further stratifying these complaints into the classifications defined by Waldinger *et al.* [181], lifelong PE was seen at rates of 2.3 and 3.18%, while the rates of acquired PE were 3.9 and 4.48%, variable PE were 8.5 and 11.38% and subjective PE were 5.1 and 6.4% [179, 180]. Both studies showed that men with acquired PE were more likely to seek treatment compared to men with lifelong PE. Treatment seeking behaviour may contribute to errors in the previously reported rates of PE, as it is possible that men with lifelong PE come to terms with their problem and not seek treatment. The additional psychological burden of a new change in ejaculatory latency in acquired PE on the other hand may prompt more frequent treatment seeking behaviours [182]. Thus, it is likely that a disparity between the incidence of the various PE sub-types in the general community and in men actively seeking treatment for PE exists [183, 184]. This disparity could be a further barrier to understanding the true incidence of each sub-type of PE. An approximately 5% prevalence of acquired PE and lifelong PE in general populations is consistent with epidemiological data indicating that around 5% of the population have an ejaculation latency of less than two minutes [185].

4.3 Other ejaculatory disorders

4.3.1 ***Delayed ejaculation***

Due to its rarity and uncertain definitions, the epidemiology of delayed ejaculation (DE) is not clear [186]. However, several well-designed epidemiologic studies revealed that its prevalence is around 3% among sexually active men [177, 187]. According to data from the NHSLS, 7.78% of a national probability sample of 1,246 men between the ages of 18 and 59 years reported "inability achieving climax or ejaculation" [177]. In a similar study where a stratified national probability sample survey completed over six months among 11,161 men and women aged 16-44 years in Britain, 0.7% of men reported the inability to reach orgasm. In an international survey of sexual problems among 13,618 men aged 40-80 years from 29 countries, 1.1 to 2.8% of men reported that they frequently experience the inability to reach orgasm [188]. Another study conducted in the United States, where a national probability sample of 1,455 men aged 57 to 85 years was recruited, 20% of men reported the inability to climax and 73% of them reported that they were bothered by this problem. [189]. Considering the findings of these epidemiologic studies and their clinical experiences, some urologists and sex therapists postulated that the prevalence of DE may be higher among older men [190-192]. Similar to the general population, the prevalence of men with the complaint of DE is also small among patients who seek treatment for their sexual problems. An Indian study that evaluated the data on 1,000 consecutive patients with sexual disorders who attended a psychosexual clinic demonstrated that the prevalence of DE was 0.6% and it was observed more frequently in elderly diabetics [193]. Nazareth *et al.* [194] evaluated the prevalence of International Classification of Diseases 10th edition (ICD-10) diagnosed sexual dysfunctions among 447 men attending 13 general practices in London, and the authors found that 2.5% of the men reported inhibited orgasm during intercourse.

4.3.2 ***Anejaculation and Anorgasmia***

Establishing the exact prevalence of anejaculation and anorgasmia is very difficult since many men cannot distinguish between ejaculation and orgasm. The rarity of these clinical conditions further hampers the attempts to conduct epidemiological studies. In a report from the USA, 8% of men reported unsuccessfully achieving orgasm during the past year [177].

According to Kinsey *et al.* [195], 0.14% of the general population have anejaculation. The most common causes of anejaculation were reported as spinal cord injury, diabetes mellitus and multiple sclerosis. Especially in most cases of spinal cord injury, medical assistance is the only way to ejaculate. While masturbation leads to the lowest rates of ejaculation, higher response rates can be obtained with penile vibratory stimulation or acetylcholine esterase inhibitors followed by masturbation in patients with spinal cord injury [196].

4.3.3 ***Retrograde ejaculation***

Similar to anejaculation, it is very difficult to estimate the true incidence of retrograde ejaculation (RE). Although RE is generally reported in 0.3% to 2% of patients attending fertility clinics [197], diabetes may increase these rates by leading autonomic neuropathy. Autonomic neuropathy results in ED and ejaculatory dysfunctions ranging from DE to RE and anejaculation, depending on the degree of sympathetic autonomic neuropathy involved [198]. In 54 diabetic patients with sexual dysfunction, RE was observed with a 6% incidence [199]. In a more recent controlled trial, RE was observed in 34.6% of diabetic men [200]. Retrograde ejaculation was also reported in studies of patients who had undergone transurethral resection of prostate (TURP) or open prostatectomy due to disrupted bladder neck integrity. In a study that investigated the effect of prostatectomy on QoL it was found that of 5,276 men after TURP, 68% reported postsurgical RE [201]. However, with the development of less invasive techniques, the incidence of RE decreases following the surgical treatment of LUTS [202, 203].

*4.3.4 **Painful ejaculation***

Painful ejaculation is a common, but poorly understood clinical phenomenon, which is associated with sexual dysfunction. Several studies demonstrated its prevalence to range between 1 and 10% in the general population [204-206]; however, it may increase to 30-75% among men who suffer from chronic prostatitis/ chronic pelvic pain syndrome (CP/CPPS) [207-211]. It should be noted that the design of the majority of these papers is not scientifically sound and the condition is probably under-reported due to the lack of an evidence-based definition and well-defined prognostic criteria.

*4.3.5 **Haemospermia***

The exact incidence and prevalence of haemospermia are difficult to elucidate due to a number of factors including its covert presentation, usually self-limiting nature and patient embarrassment. The symptom represents approximately 1-1.5 % of all urological referrals and occurs in all age groups with a mean age of 37 years [212, 213]. In a PCa screening study of 26,126 men, ~ 50 years or older than 40 with a history of PCa or of black ethnicity, haemospermia was found in 0.5% on entry to the trial [214].

4.4 Low sexual desire

The global prevalence of low sexual desire in men ranged from 3-28% [188, 215, 216]. Overall, low solitary versus low dyadic sexual desire, have been reported in 68% and 14% of men, respectively [217]. Also, low sexual desire has been observed as a common complaint in gay men, with its prevalence ranging from 19% to 57% [218, 219]. Despite its relationship with age, low sexual desire has been reported even among young men (i.e., 18-29 years old), with prevalence rates ranging from 6% to 19% [177, 220, 221].

Table 7: The prevalence rates of erectile dysfunction [165]

Date	Authors	Population	Response rate	Age (years)	Measurement technique	Principal findings	Correlates
1993	Solstad *et al.* [222, 223]	439 men; random population sample (Denmark)	81%	51	Interview and self-administered questionnaire	Overall, 4% of men had ED as assessed by questionnaire Interviews identified a higher frequency of sexual dysfunction	Not reported
1994	Feldman *et al.* [166] **MMAS*	1,290 men; random population sample (United States)	40%	40-70	Self-administered questionnaire	Overall, 52% of men had ED 17.2% of men had minimal ED 25.2% of men had moderate ED 9.6% of men had complete ED	Age
1995	Panser *et al.* [224]	2,155 men; random population sample (United States)	55%	40-79	Self-administered questionnaire	1% ED in men aged 40-49 years 6% ED in men aged 50-59 years 22% ED in men aged 60-69 years 44% ED in men aged 70-79 years	
1996	Helgason *et al.* [225]	319 men; random population sample (Sweden)	73%	50-80	Self-administered questionnaire	3% ED in men aged 50-59 years 24% ED in men aged 60-69 years 49% ED in men aged 70-80 years	Age, Prostate cancer, Diabetes, Myocardial infarction, Diuretic use, Warfarin use, H2 receptor blocker use

1996	MacFarlane *et al.* [226]	1,734 men; random population sample (France)	86%	50-80	Self-administered questionnaire	20% ED in men aged 50-59 years 33% ED in men aged 60-69 years 38% ED in men aged 70-80 years	Age
1996	Fugl-Meyer [215]	1,288 men; random population sample men (Sweden)	52%	18-74	Structured interview	Overall, 5% of men had ED 3% ED in men aged 18-24 years 2% ED in men aged 25-34 years 2% ED in men aged 35-49 years 7% ED in men aged 50-65 years 24% ED in men aged 66-74 years	Age
1999	Laumann *et al.* [177] **NHSLS*	1,244 men; random population sample (United States)	70%	18-59	Structured interview	Overall, 10% of men had ED (moderate plus severe) 7% ED in men aged 18-29 years 9% ED in men aged 30-39 years 11% ED in men aged 40-49 years 18% ED in men aged 50-59 years	Age, Race, Emotional stress, Urinary symptoms, Poor health, Low income
1999	Pinnock *et al.* [227]	427 men; random population sample (Australia)	69.8%	> 40	Self-administered questionnaire	6% ED in men aged 40-49 years 12% ED in men aged 50-59 years 41% ED in men aged 60-69 years 63% ED in men aged 70-79 years 81% ED in men aged 80+ years	Age, Hyper-cholesterolemia,
2000	Braun *et al.* [167] (COLOGNE Study)	8,000 men	56%	30-80	The self-administered questionnaire by mail (Cologne ED Questionnaire)	The prevalence of ED was 19.2%	Age, Hypertension, Diabetes, Pelvic surgery, LUTS
2001	Moreira *et al.* [228]	1,170 men; attending public places (heavy bias toward younger men) (Brazil)	91%	>18	Self-administered questionnaire	Overall, 14.7% of men had ED (moderate plus severe); 9.4% ED in men aged 18-39 years 15.5% ED in men aged 40-49 years 22.1% ED in men aged 50-59 years 37% ED in men aged 60-69 years 39.6% ED in men aged >70 years	Age, Education, Racial origin, Diabetes, Hypertension, Depression

2001	Meuleman *et al.* [229]	1,233 men; random population sample (the Netherlands)	70%	40-79	Self-administered questionnaire	Overall, 13% of men had ED 6% ED in men aged 40-49 years 9% ED in men aged 50-59 years 22% ED in men aged 60-69 years 38% ED in men aged 70-79 years	Age
2001	Blanker *et al.* [205, 230]	1,688 men; random population sample (the Netherlands)	50%	50-75	Self-administered questionnaire	3% ED in men aged 50-54 years 5% ED in men aged 55-59 years 11% ED in men aged 60-64 years 19% ED in men aged 65-69 years 26% ED in men aged 70-78 years	Age, Smoking, Obesity, LUTS, COPD, Treatment for CV disease
2001	Martin-Morales *et al.* [231]	2,476 men; random population sample (Spain)	75%	25-70	Self-administered questionnaire and single question	Overall, 12.1% of men had ED (single question) and 18.9% for questionnaire According to single question: 3.9% ED in men aged 25-39 years 6.3% ED in men aged 40-49 years 15.9% ED in men aged 50-59 years 32.2% ED in men aged 60-70 years IIEF identified more mild ED, and single question identified more moderate and severe ED	Age, Hypertension, Diabetes, Cardiac disease, Pulmonary disease, Circulatory disease, Rheumatic disease, High cholesterol, Prostatic disease, Allergy, Medication "for nerves", Sleeping tablets, Heavy smoking, Alcohol abuse
2002	Moreira *et al.* [232]	602 men; random population sample (Brazil)	92%	40-70	Interview	Overall, 14.4% of men had ED (moderate or severe) 9.9% ED in men aged 40-49 years 11.8% ED in men aged 50-59 years 31.7% ED in men aged 60-69 years	Age, Marital status, Diabetes, Depression, IPSS, Decreased physical activity

2002	Moreira *et al.* [233]	342 men; random population sample (Brazil)	47.6%	40-70	Self-administered questionnaire	Overall, 12.0% of men had ED (moderate or severe) 3.5% ED in men aged 40-49 years 16.7% ED in men aged 50-59 years 39.6% ED in men aged 60-69 years	Age, Diabetes, Hypertension, Heavy smoking
2002	Morillo *et al.* [234]	1,963 men; random population sample (Columbia, Venezuela and Ecuador)	82%	> 40	Standardised questionnaire	Overall, 19.8% of men had ED (moderate or severe)	Age, Diabetes, Hypertension, BPH
2003	Richters *et al.* [235]	8,517 men; random population sample (Australia)	69.4%	16-59		Overall, 9.5% of men had ED 4.3% ED in men aged 16-19 years 4.5% ED in men aged 20-29 years 5.1% ED in men aged 30-39 years 12.5% ED in men aged 40-49 years 19.2% ED in men aged 50-59 years	Age
2003	Rosen *et al.* [236]	12,815 men; random population sample (multinational: United States, United Kingdom, France, Germany, the Netherlands, Italy, Spain)	36.8%	50-80	Self-administered questionnaire (IIEF and DAN-PSS)	According to DAN-PSS: Overall, 48.9% of men had ED 30.8% ED in men aged 50-59 years 55.1% ED in men aged 60-69 years 76% ED in men aged 70-80 years	Age, LUTS, Diabetes, Hypertension, Cardiac disease, Hyperlipidemia, Tobacco use
2004	Rosen *et al.* [237] **MALES*	27,839 men random population sample (multinational: United States, United Kingdom, Germany, France, Italy, Spain, Mexico, and Brazil)	US: 45%; UK: 48%; Germany: 45%; France: 48%; Italy: 53%; Spain: 50%; Mexico: 55% and Brazil: 51%.	20-75	Random digit dialing and interviewed via computer-assisted telephone interviewing. A standardised questionnaire	The overall prevalence of ED in the MALES sample was 16%	Age, High blood pressure, Heart trouble or angina, High cholesterol, Diabetes, Depression or anxiety

2004	Shiri *et al.* [238]	2,198 men; stratified birth cohort (Finland)	70%	50,60, and 70 at first survey 55, 65, and 75 at second survey	Self-administered questionnaire at two separate time points, 5 years apart	48% of men had minimal ED 15.2% of men had moderate ED 13.2% of men had complete ED	Age, Diabetes, Hypertension, Heart disease, Cerebrovascular disease, Smoking
2005	Laumann *et al.* [188] **GSSAB*	13,750 men; random population sample (world)	19%	40-80	Telephone survey (random dialed digit)	Overall: In Northern Europe, 13.3% had ED In Southern Europe, 12.9% had ED In non-European West, 20.6% had ED In Central/South America, 13.7% had ED In Middle East, 14.1% had ED In East Asia, 13.3% had ED In Southeast Asia, 28.1% had ED	Age
2005	Moreira *et al.* [239]	750 men; random population sample (Spain)	23%	40-80	Telephone survey (random digit dialing)	Overall, 12.7% had ED	Age
2005	Moreira *et al.* [240]	750 men; random population sample (Germany)	17.4%	40-80	Telephone survey (random digit dialing)	Overall, 7.9% had ED	Age
2005	Moreira Junior *et al.* [241]	471 men; random population sample (Brazil)	18%	40-80	Telephone survey (random digit dialing)	Overall, 13.1% of men had ED	Age, Depression
2006	Brock *et al.* [242]	500 men; random population sample (Canada)	9.7%	40-80	Telephone survey (random digit dialing)	Overall, 16% of men had ED	Age, Depression, Diabetes
2007	De Almeida Claro *et al.* [243]	2,000 men; random population study (Brazil)	Not reported	>20	Standardised interview with self-reported questionnaire (IIEF)	Overall, 1.7% of men had ED 0.2% ED in men aged 20-30 years 0.22% ED in men aged 31-40 years 1.0% ED in men aged 41-50 years 2.8% ED in men aged 51-60 years 7.0% ED in men aged > 61 years	Age

2007	Ahn *et al.* [244]	1,570 men; geographically stratified random population study	Not reported	40-79	Self-administered questionnaire (IIEF-5)	Overall, 13.4% had self-reported ED ED prevalence as defined by IIEF-5 score less than 17 was 32.4% According to single question: 4.2% ED in men aged 40-49 years 13.0% ED in men aged 50-59 years 30.1% ED in men aged 60-69 years 41.1% ED in men aged 70-79 years	Age, Single status, Low income, Diabetes, Hypertension, Hyperlipidemia, Heart disease, Musculoskeletal disorders, Alcohol, Depression, Coffee intake
2008	Moreira *et al.* [245]	750 men; random population sample (Australia)	16.9%	40-80	Telephone survey (random digit dialing)	Overall, 32% of men had ED	Age
2008	Chew *et al.* [246]	1,580 men; random population sample (Australia)	37.3%	>20	Postal survey Self-administered questionnaire (IIEF-5)	15.7% ED in men aged 20-29 years 8.7% ED in men aged 30-39 years 12.9% ED in men aged 40-49 years 31.6% ED in men aged 50-59 years 52.4% ED in men aged 60-69 years 69.4% ED in men aged 70-79 years 68.2% ED in men aged > 80 years	Age, Marital status
2008	Teles *et al.* [247]	3,067 men; random population sample (Portugal)	81.3%	40-69	Self-administered questionnaire, including IIEF	Overall, 48.1% of men had ED 29% ED in men aged 40-49 years 50% ED in men aged 50-59 years 74% ED in men aged 60-69 years	Age, Diabetes, Cardiac insufficiency, Psychiatric illness
2008	Moreira *et al.* [248]	750 men; random population sample (United Kingdom)	17%	40-80	Telephone survey (random digit dialing)	Overall, 17.8% of men had ED	Age
2009	Laumann *et al.* [249]	742 men; random population sample (United States)	9%	40-80	Telephone survey (random digit dialing)	Overall, 22.5% of men had ED	Age, Depression
2009	Buvat *et al.* [250]	750 men; random population sample (France)	23.8%	40-80	Telephone survey (random digit dialing)	Overall, 15% of men had ED	Age

2010	Corona *et al.* [251]	3,369 men; random population study (Europe: Italy, Belgium, United Kingdom, Spain, Poland, Hungary, Estonia)	40%	40-80	Self-administered questionnaire	Overall, 30% of men had ED 6% ED in men aged 40-49 years 19% ED in men aged 50-59 years 38% ED in men aged 60-69 years 64% ED in men 70 and over	Age, Depression, LUTS, Cardiovascular disease, Diabetes, Obesity
2016	Oyelade *et al.* [252]	241 men; random sampling cross-sectional population based survey (Nigeria)	99%	30-80	Self-administered questionnaire (IIEF-5)	The general prevalence of ED in this study was 58.9%	Age, Hypertension, Use of anti-hypertensive drugs, Diabetes mellitus, Heart disease
2017	Cayan *et al.* [253]	2,760 men; random population study (Turkey)	Non-reported	≥ 40	Self-administered questionnaire (IIEF-5)	The prevalence of ED was calculated as 33% among all males of ≥ 40 years of age. ED prevalence rates were 17% for 40-49 years, 35.5% for 50-59 years, 68.8% for 60-69 years, and 82.9% for ≥ 70 years	Age, Diabetes, Hypertension, Atherosclerosis, Dyslipidemia, LUTS, Educational status, Monthly income
2017	Quilter *et al.* [254]	Randomly selected age-stratified population-based sample of 2,000 men (New Zealand)	30%	40-70	Self-reported erectile function (IIEF-5) and a single-question self-assessment tool.	Prevalence of ED was 42% (22% mild, 10% mild to moderate, 6% moderate, and 4% severe)	Age, Anxiety or depression

** Four baseline study estimating the prevalence of Erectile Dysfunction:*
MMAS = the Massachusetts Male Aging Study; NHSLS = the National Health of Social Life Survey; MALES = the multi-national men's attitudes to life events and sexuality; GSSAB = Global Study of Sexual Attitudes and Behaviours.
BPH = Benign Prostate Hyperplasia; COPD = Chronic Obstructive Pulmonary Disease; ED = Erectile Dysfunction; IIEF = International Index of Erectile Function; IPSS = International Prostate Symptom Score; LUTS = Lower urinary tract symptoms.

Table 8: The prevalence rates of premature ejaculation [171]

Date	Authors	Method of Data Collection	Method of Recruitment	Operational Criteria	Prevalence Rate	Number of Men
1998	Dunn *et al.* [255]	Mail	General practice registers - random stratification	Having difficulty with ejaculating prematurely	14% (past 3 mo)	617
					31% (lifetime)	618
1999	Laumann *et al.* (NHSLS) [177]	Interview	NA	Climaxing/ ejaculating too rapidly during the past 12 months	31%	1,410
2002	Fugl-Meyer and Fugl-Meyer [256]	Interview	Population register	NA	9%	1,475
2004	Rowland *et al.* [257]	Mailed questionnaire	Internet panel	DSM IV	16.3%	1,158
2004	Nolazco *et al.* [258]	Interview	Invitation to outpatient clinic	Ejaculating fast or prematurely	28.3%	2,456
2005	Laumann *et al.* [188]	Telephone-personal interview/Mailed questionnaires	Random (systematic) sampling	Reaching climax too quickly during the past 12 months	23.75% (4.26% frequently)	13,618
2005	Basile Fasolo *et al.* [259]	Clinician-based	Invitation to outpatient clinic	DSM IV	21.2%	12,558
2005	Stulhofer *et al.* [260]	Interview	Stratified sampling	Often ejaculating in less than 2 minutes	9.5%	601
2007	Porst *et al.* (PEPA) [178]	Web-based survey Self-report	Internet panel	Control over ejaculation, Distress	22.7%	12,133
2008	Shindel *et al.* [261]	Questionnaire	Male partners of infertile couples under evaluation	Self-report premature ejaculation	50%	73
2009	Brock *et al.* [262]	telephone interview	Web-based survey	DSM III	16%	3,816
				Control	26%	
				Distress	27%	
2010	Traeen and Stigum [221]	Mailed questionnaire + internet	Web interview + Randomisation		27%	11,746+1,671
2010	Son *et al.* [263]	Questionnaire	Internet panel (younger than 60)	DSM IV	18.3%	600
2010	Amidu *et al.* [264]	Questionnaire	NA	NA	64.7%	255
2010	Liang *et al.* [265]	NA	NA	ISSM	15.3%	1,127
2010	Park *et al.* [266]	Mailed questionnaire	Stratified sampling	Suffering from PE	27.5%	2,037
2010	Vakalopoulos *et al.* [267]	One-on-one survey	Population based cohort	EED	58.43%	522
				ISSM Lifelong PE	17.7%	
2010	Hirshfeld *et al.* [218]	Web-based survey	Online advertisement in the United States and Canada	Climaxing/ ejaculating too rapidly during the past 12 months	34%	7,001
2011	Christensen *et al.* [268]	Interview + questionnaire	Population register (random)	NA	7%	5,552
2011	Serefoglu *et al.* [179]	Interview	Stratified sampling	Complaining about ejaculating prematurely	20.0%	2,593

2011	Son *et al.* [269]	Questionnaire	Internet panel	Estimated IELT ≤ 5 mins, inability to control ejaculation, distress	10.5%	334
2011	Tang and Khoo [270]	Interview	Primary care setting	PEDT ≥ 9	40.6%	207
2012	Mialon *et al.* [271]	Mailed questionnaire	Convenience sampling (18-25 years old)	Control over ejaculation Distress	11.4%	2,507
2012	Shaeer and Shaeer [272]	Web-based survey	Online advertisement in Arabic countries	Ejaculate before the person wishes to ejaculate at least sometimes	83.7%	804
2012	Shindel *et al.* [273]	Web-based survey	Online advertisement targeted to MSM + distribution of invitation to organisations catering to MSM	PEDT ≥ 9	8-12%	1,769
2012	McMahon *et al.* [274]	Computer assisted interviewing, online, or in-person self-completed	NA	PEDT ≥ 11	16%	4,997
				Self-Reported (always/nearly-always)	13%	
2012	Lotti *et al.* [275]	Interview	Men seeking medical care for infertility	PEDT ≥ 9	15.6%	244
2013	Zhang *et al.* [276]	Interview	Random stratified sample of married men aged 30-60	Self-reported premature ejaculation	4.7%	728
2013	Lee *et al.* [277]	Interview	Stratified random sampling	PEDT ≥ 11	11.3%	2,081
				Self-Reported	19.5%	
				IELT<1 min	3%	1,035
2013	Gao *et al.* [180]	Interview	Random stratified sample of monogamous heterosexual men in China	Self-reported premature ejaculation	25.8%	3,016
2013	Hwang *et al.* [278]	Survey of married couples	Married heterosexual couples in Korea	Estimated IELT < 2 minutes	21.7%	290
				PEDT > 11	12.1%	
2013	Vansintejan *et al.* [279]	Web Based survey	Online and flyer advertisements to Belgian men who have sex with men (Only HIV+ men in this study)	IPE score < 50% of total possible	4%	72
2013	Shaeer *et al.* [280]	Web Based survey	Targeting English-speaking males above the age of 18, living most of their lives in the USA, regardless of personal interests and web browsing preferences	ISSM definition [175]	6.3%	1133
				PEDT	49.6%	
				Unfiltered self-reported	77.6%	
				Filtered self-reported	14.4%	

2016	Karabakan [281]	Interview (heavy bias toward younger men)	Targeting police academy students aged 24-30 who applied for routine urological examination	PEDT > 10	9.2%	1000
2017	Gao *et al.* [282]	Field survey with face-to-face interviews	Comprising men aged 20-68 years in five cities in the Anhui province	Self-estimated IELT	Lifelong PE 10.98% Acquired PE 21.39%	1239

DMS = Diagnostic and Statistical Manual of Mental Disorders; NA = not applicable; ISSM = International Society for Sexual Medicine; PEDT = Premature Ejaculation Diagnostic Tool; IELT = intravaginal ejaculatory latency time; IPE = Index of Premature Ejaculation; mo = months.

5. MANAGEMENT OF ERECTILE DYSFUNCTION

5.1 Definition and classification

Penile erection is a complex physiological process, which involves integration of both neural and vascular events, along with an adequate endocrine milieu. It involves arterial dilation, trabecular smooth muscle relaxation and activation of the corporeal veno-occlusive mechanism [283]. Erectile dysfunction is defined as the persistent inability to attain and maintain an erection sufficient to permit satisfactory sexual performance [284]. Erectile dysfunction may affect psychosocial health and have a significant impact on the QoL of patients and their partner's [166, 285-287].

There is increasing evidence that the presence of ED increases the risk of future CV events including MI, cerebrovascular events, and all-cause mortality, with a trend towards an increased risk of cardiovascular mortality [288]. Therefore, ED can be an early manifestation of coronary artery and peripheral vascular disease and should not be regarded only as a QoL issue, but also as a potential warning sign of CVD [289-291]. A cost analysis showed that screening men presenting with ED for CVD represents a cost-effective intervention for secondary prevention of both CVD and ED, resulting in substantial cost savings relative to identification of CVD at the time of presentation [292].

Erectile dysfunction is commonly classified into three groups based on aetiology. These include organic, psychogenic and mixed ED. However, this classification should be used with caution as most cases are actually of mixed aetiology. It has therefore been suggested to use the terms "primary organic" or "primary psychogenic".

5.2 Risk factors

Erectile dysfunction is associated with unmodifiable and modifiable common risk factors including age, diabetes mellitus, dyslipidaemia, hypertension, CVD, BMI/obesity, MetS, hyperhomocysteinemia, lack of exercise, and smoking (a positive dose-response association between quantity and duration of smoking has been demonstrated) [286, 290, 293-300]. Furthermore, an association between ED status and pharmaco-therapeutic agents for CVD (e.g., thiazide diuretics and β-blockers, except nebivolol, exert detrimental effects on erectile function, whereas newer drugs i.e., angiotensin-converting enzyme (ACE)-inhibitors, angiotensin-receptor-blockers and calcium-channel-blockers have neutral or even beneficial effects) [290, 301, 302], atrial fibrillation [303], hyperthyroidism [20], vitamin D deficiency [304, 305], hyperuricemia [306], and depression [307] have also been reported as risk factors. Available data do not confirm a clear association between ED and hypothyroidism and hyperprolactinaemia [20].

A number of studies have shown that lifestyle modification [308], including physical activity [309], weight loss [310] and pharmacotherapy [302, 311, 312] for CVD risk factors may be of help in improving sexual function in men with ED. Meta-analytic data reveals a positive effect of lipid-lowering therapy with statins on erectile function [313, 314]. However, it should be emphasised that further controlled prospective studies are necessary to determine the effects of exercise or other lifestyle changes in the prevention and treatment of ED [308].

Further epidemiological data have also highlighted other potential risk factors associated with ED including sleep disorders [315], obstructive sleep apnoea [316], psoriasis [317-319], gouty arthritis [320] and ankylosing spondylitis [321], non-alcoholic fatty liver disease [322], other chronic liver disorders [323], chronic periodontitis [324], open-angle glaucoma [325], inflammatory bowel disease [326], chronic fatigue syndrome [327] and allergic rhinitis [328].

Erectile dysfunction is also frequently associated with other urological conditions and procedures (Table 9). Epidemiological studies have also demonstrated consistent evidence for an association between LUTS/BPH and sexual dysfunction, regardless of age, other comorbidities and lifestyle factors [329]. The Multinational Survey on the Aging Male study, performed in the USA, France, Germany, Italy, Netherlands, Spain, and the UK, systematically investigated the relationship between LUTS and sexual dysfunction in over 12,000 men aged 50-80 years. In the 83% of men who were reported to be sexually active, the overall prevalence of LUTS was 90%, with the overall prevalence of ED 49%, with a reported complete absence of erections in 10% of patients. Moreover, the overall prevalence of ejaculatory disorders was 46% [236]. Regardless of the technique used, surgery for BPH-LUTS had no significant impact on erectile function. In fact, even an improvement was found depending on the degree of improvement of urinary symptoms [330, 331]. An association between ED and CP/CPPS [332], and bladder pain syndrome/interstitial cystitis has been confirmed, mostly in younger men [333]. Furthermore, a relevant interplay and association between ED and PE has also been demonstrated (section 6.2) [334]. An increased risk of ED is reported following transrectal ultrasound (TRUS)-guided prostate biopsy [335] and after open urethroplasty, especially for correction of posterior strictures [336].

Table 9: Urological conditions associated with ED

Urological Condition	Association with ED
LUTS/BPH [329]	Depending on the severity of LUTS and patients' age/population characteristics: Odds ratio (OR) of ED among men with LUTS/BPH ranges from 1.52 to 28.7 and prevalence ranges from 58% to 80%
Surgery for BPH/LUTS (TUR-P, laser, open, laparoscopic, etc.) [330]	Overall, absence of significant variations in terms of erectile function scores after surgery
Chronic Prostatitis/Chronic Pelvic Pain Syndrome [332]	Prevalence of ED among patients with CP/CPPS 29% [24%-33%, 95%CI], Range: 11% - 56% among studies
Bladder Pain Syndrome/Interstitial Cystitis [333]	OR of BPS/IC among patients with ED. Overall: OR (adjusted) = 1.75 [1.12 - 2.71, 95%CI] Age ≥ 60: OR (adjusted) = 1.07 [0.41 - 2.81, 95%CI] Age 40-59: OR (adjusted) = 1.44 [1.02 - 2.12, 95%CI] Age 18-39: OR (adjusted) = 10.40 [2.93 - 36.94, 95%CI]
Premature Ejaculation [334]	OR of ED among patients with PE = 3.68 [2.61 - 5.68, 95%CI]
Urethroplasty surgery for posterior urethral strictures [336]	OR of ED after posterior urethroplasty = 2.51 [1.82 - 3.45, 95%CI]

5.3 Pathophysiology

The pathophysiology of ED may be vasculogenic, neurogenic, anatomical, hormonal, drug-induced and/or psychogenic (Table 10) [283]. In most cases, numerous pathophysiology pathways can co-exist and may all negatively impact on erectile function.

The proposed ED etiological and pathophysiological division should not be considered prescriptive. In most cases, ED is associated with more than one pathophysiological factor and very often, if not always, will have a psychological component. Likewise, organic components can negatively impact on erectile function with different pathophysiological effects. Therefore, Table 10 must be considered for diagnostic classifications only (along with associated risk factors for each subcategory).

Table 10: Pathophysiology of ED

Vasculogenic
Recreational habits (i.e., cigarette smoking)
Lack of regular physical exercise
Obesity
Cardiovascular diseases (e.g. hypertension, coronary artery disease, peripheral vasculopathy)
Type 1 and 2 diabetes mellitus; hyperlipidaemia; metabolic syndrome; hyperhomocysteinemia
Major pelvic surgery (e.g., radical prostatectomy) or radiotherapy (pelvis or retroperitoneum)
Neurogenic
Central causes
Degenerative disorders (e.g., multiple sclerosis, Parkinson's disease, multiple atrophy, etc.)
Spinal cord trauma or diseases

Stroke
Central nervous system tumours
Peripheral causes
Type 1 and 2 diabetes mellitus
Chronic renal failure; chronic liver failure
Polyneuropathy
Surgery (major surgery of pelvis/retroperitoneum) or radiotherapy (pelvis or retroperitoneum)
Surgery of the urethra (urethral stricture, urethroplasty, etc.)
Anatomical or structural
Hypospadias; epispadias; micropenis
Phimosis
Peyronie's disease
Penile cancer (other tumours of the external genitalia)
Hormonal
Diabetes mellitus; Metabolic Syndrome;
Hypogonadism (any type)
Hyperthyroidism
Hyper- and hypocortisolism (Cushing's disease, etc.)
Panhypopituitarism and multiple endocrine disorders
Mixed pathophysiology pathways
Chronic systemic diseases (e.g., diabetes mellitus, hypertension, metabolic syndrome, chronic renal failure, chronic liver disorders, hyperhomocysteinemia, hyperuricemia, etc.)
Psoriasis; gouty arthritis; ankylosing spondylitis; non-alcoholic fatty liver; chronic periodontitis; open-angle glaucoma; inflammatory bowel disease, chronic fatigue syndrome, allergic rhinitis, obstructive sleep apnoea, depression
Iatrogenic causes (e.g. TRUS-guided prostate biopsy, etc.)
Drug-induced
Antihypertensives (i.e., thiazidediuretics, beta-blockers)*
Antidepressants (selective serotonin reuptake inhibitors, tricyclics)
Antipsychotics
Antiandrogens (GnRH analogues and antagonists; 5-ARIs)
Recreational drugs (e.g., heroin, cocaine, marijuana, methadone, synthetic drugs, anabolic steroids, excessive alcohol intake, etc.)
Psychogenic
Generalised type (e.g., lack of arousability and disorders of sexual intimacy)
Situational type (e.g., partner-related, performance-related issues or due to distress)
Trauma
Penile fracture
Pelvic fractures

GnRH = gonadotropin-releasing hormone; 5-ARIs = 5α-reductase inhibitors.

*A symmetry analysis showed that cardiovascular drugs do not strongly affect the risk of subsequently being prescribed as an anti-erectogenic drug. The analysis only assessed the short-term risk. [337].

*5.3.1 **Pelvic surgery and prostate cancer treatment***

Pelvic surgery, especially for oncological disease (e.g., radical prostatectomy (RP) [338] or radical cystectomy [339] and colorectal surgery [340]), may have a negative impact on erectile function and overall sexual health. The most relevant causal factor is a lesion (any) occurring to the neurovascular bundles that control the complex mechanism of the cavernous erectile response, whose preservation (either partial or complete) during surgery eventually configures the so-called nerve-sparing (NS) approach. Thereof, surgery resulting in damage of the neurovascular bundles, will result in ED, although NS approaches have been adopted over the last a few decades. This approach is applicable to all types of surgery that are potentially harmful to erectile function, although to date, only the surgical treatment of PCa has enough scientific evidence supporting its potential pathophysiological association with ED [341-343]. However, even non-surgical treatments of PCa (i.e., radiotherapy; brachytherapy) can be associated with an impairment of erectile function. The concept of an active surveillance (AS) strategy for the treatment of PCa was developed to avoid over-treatment of non-significant localised low-risk diseases, while limiting potential functional side-effects (including ED). However, it is interesting that data suggest that even AS may have a detrimental impact on erectile function (and sexual well-being as a whole) [344-346].

To date the most robust data on patient-reported outcome measures (PROMS) including erectile function, comparing treatments for clinically localised PCa come from the Prostate Testing for Cancer and Treatment (ProtecT) trial where 1,643 patients were randomised to active treatment (either RP or RT) and active monitoring (AM) and were followed-up for six years [347]. Sexual function, including erectile function, and the effect of sexual function on QoL outcomes were assessed with the Expanded Prostate Cancer Index Composite with 26 items (EPIC-26) instrument [348, 349]. At baseline, 67% of men reported erections firm enough for sexual intercourses this fell to 52% in the AM group, 22% in the RT group, and to 12% in the RP group, at six-month assessment. Interestingly, the worst trend over time was recorded in the RP group (with 21% erections firm enough for intercourse after three years versus 17% after six years). In the RT group, the percentage of men reporting erections firm enough for intercourse increased between six and twelve months, with a subsequent further decrease to 27% at six-year assessment. The percentage declined over time on a yearly basis in the AM group, with 41% of men reporting erections firm enough for intercourse at three-year and 30% at six-year evaluation [347].

Radical prostatectomy (either open, laparoscopic or robot-assisted) is a widely performed procedure with a curative intent for patients presenting with clinically localised intermediate- or high-risk PCa and a life expectancy of more than ten years based on health status and comorbidities [350, 351]. This procedure may lead to treatment-specific sequelae affecting health-related QoL. Men undergoing RP (any technique) should be adequately informed before the operation that there is a significant risk of sexual changes other than ED, including decreased libido, changes in orgasm, anejaculation, Peyronie's-like disease, and changes in penile length [343]. These outcomes have become increasingly important with the more frequent diagnosis of PCa in both younger and older men [352-354]. Overall, research has shown that 25-75% of men experience post-RP ED [355], even though these findings suffer from methodological flaws, in particular, the heterogeneity of reporting and assessment of ED in the studies [341, 356]. Conversely, the rate of unassisted post-operative erectile function recovery is in the range of between 20 and 25% in most studies; these rates do not appear to have substantially improved or changed over the past seventeen years, despite the growing attention to post-surgical rehabilitation protocols and the refinement of surgical techniques [356-358].

Overall, patient age, baseline erectile function and surgical volume, with the consequent ability to preserve the neurovascular bundles, seem to be the main factors in promoting the highest rates of post-operative potency [342, 353, 355, 359]. Patients being considered for nerve-sparing RP (NSRP) should ideally be potent pre-operatively [352, 353]. Overall, the recovery time following surgery is of major clinical importance in terms of post-operative recovery of erectile function. Available data confirms that post-operative erectile function recovery can occur up to 48 months after RP [360]. Likewise, it has been suggested that post-operative therapy (any type) should be commenced as close as possible to the surgical procedure [352, 355], although evidence suggests that the number of patients reporting return of spontaneous erectile function has not actually increased.

In terms of the effects of surgical interventions (e.g., robot-assisted RP [RARP] versus other types of surgery), the data is still conflicting. An early systematic review showed a significant advantage in favour of RARP in comparison with open retropubic RP in terms of twelve-month potency rates [361], without significant differences between laparoscopic RP and RARP. Some recent reports confirm that the probability of erectile function recovery is about twice as high for RARP compared with open RP [362]. More recently, a prospective, controlled, non-randomised trial of patients undergoing RP in fourteen Swedish centres comparing RARP versus open retropubic RP, showed a small improvement with respect to erectile function after RARP [363]. Conversely, a randomised controlled phase 3 study of men assigned to open RP or RARP showed that the two techniques yielded similar functional outcomes at twelve weeks [364]. As a whole, more controlled prospective well-designed studies, with longer term follow-up, are necessary to determine if RARP is superior to open RP in terms of post-operative ED rates [365]. Furthermore, to overcome the problem of heterogeneity in the assessment of erectile function, for which there is variability in terms of the PROMS used (IIEF, IIEF-5, EPIC 26, Sexual Health Inventory for Men, etc.) to measure potency or erectile function; the criteria used to define restoration of erectile function should be re-evaluated utilising objective and validated thresholds (e.g., normalisation of scores or return to baseline erectile function) [341].

Erectile dysfunction is also a common problem after both external beam radiation therapy (EBRT) and brachytherapy for PCa. A systematic review and meta-analysis including men treated with EBRT (65%), brachytherapy (31%) or both (4%) showed that the post-treatment prevalence of ED is 34% at 1 year and 57% at 5.5 years, respectively [366, 367]. Similar findings have been reported for stereotactic radiotherapy with 26-55% of previously sexually functioning patients reporting ED at 60 months [368].

Recently other modalities have emerged as potential therapeutic options in patients with clinically-localised PCa, including whole gland and focal (lesion-targeted) treatments, in order to ablate tumours selectively whilst limiting sexual toxicity by sparing the neurovascular bundles. These include high-intensity focused US (HIFU), cryotherapeutic ablation of the prostate (cryotherapy), focal padeliporfin-based vascular-targeted photodynamic therapy, and focal radiation therapy (RT) by brachytherapy or CyberKnife®. Overall, all these approaches have been shown to have a less negative impact on erectile function, although all these approaches lack robust mid- and long-term oncological outcomes and prospective randomised controlled studies are needed to compare functional and oncological outcomes between the treatment modalities [369, 370].

*5.3.2 **Summary of evidence on the epidemiology/aetiology/pathophysiology of ED***

Summary of evidence	**LE**
Erectile dysfunction is common worldwide.	2b
Erectile dysfunction shares common risk factors with cardiovascular disease.	2b
Lifestyle modification (regular exercise and decrease in BMI) can improve erectile function.	1b
Erectile dysfunction is a symptom, not a disease. Some patients may not be properly evaluated or receive treatment for an underlying disease or condition that may be causing ED.	4
Erectile dysfunction is common after RP, irrespective of the surgical technique used.	2b
Erectile dysfunction is common after external radiotherapy and brachytherapy.	2b
Erectile dysfunction is less common after cryotherapy and high-intensity focused US.	2b

5.4 Diagnostic evaluation (basic work-up)

*5.4.1 **Medical and sexual history***

The first step in evaluating ED is always a detailed medical and sexual history of patients and when available their partners [371]. It is important to establish a relaxed atmosphere during history-taking; this will make it easier to ask questions about erectile function and other aspects of the patient's sexual history; and to explain the diagnosis and therapeutic approach to the patient and their partner. Figure 3 lists the minimal diagnostic evaluation (basic work-up) in patients with ED.

The sexual history must include information about previous and current sexual relationships, current emotional status, onset and duration of the erectile problem, and previous consultations and treatments. The sexual health status of the partner(s) (when available) can also be useful. A detailed description should be made of the rigidity and duration of both sexually-stimulated and morning erections and of problems with sexual desire, arousal, ejaculation, and orgasm [372, 373]. Validated psychometric questionnaires, such as the IIEF [80] or its short version the SHIM [80], help to assess the different sexual function domains (i.e. sexual desire, erectile function, orgasmic function, intercourse, and overall satisfaction), as well as the potential impact of a specific treatment modality. Similarly, structured interview have been demonstrated to allow the identification and quantification of the different underlining factors impacting upon erectile function [374].

Psychometric analyses also support the use of the Erectile Hardness Score for the assessment of penile rigidity in practice and in clinical trials research [375]. In cases of depressive mood, clinicians may use the Beck Depressive Inventory [376], which is one of the most recognised self-reported measures in the field, takes approximately ten minutes to complete, and assigns the patient to a specific level of depression (varying from "normal mood" to "extreme depression").

Patients should always be screened for symptoms of possible hypogonadism (testosterone deficiency), including decreased energy, libido, and fatigue; potential cognitive impairment may be also observed in association with hypogonadism (see sections 3.5 and 3.6), as well as for LUTS. In this regard, although LUTS/BPH in itself does not represent a contraindication to treat a patient for LOH, screening for LUTS severity is clinically relevant [7].

*5.4.2 **Physical examination***

Every patient must be given a physical examination focused on the genitourinary, endocrine, vascular and neurological systems [377, 378]. A physical examination may reveal unsuspected diagnoses, such as Peyronie's disease, pre-malignant or malignant genital lesions, prostatic enlargement or irregularity/nodularity, or signs and symptoms suggestive for hypogonadism (i.e., small testes, alterations in secondary sexual characteristics etc.).

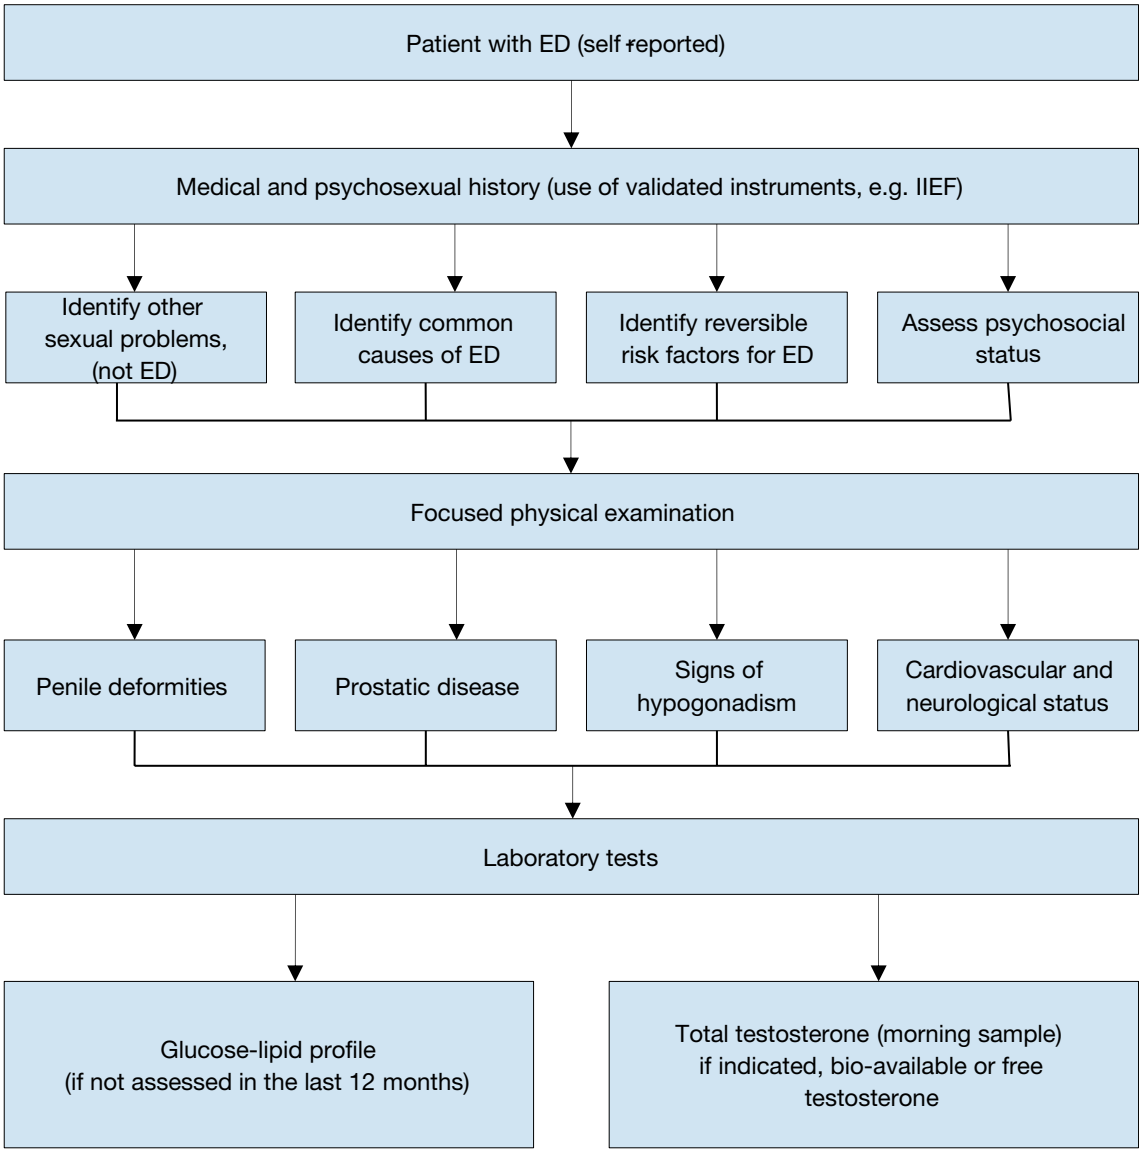
Overall, assessing previous or concomitant penile abnormalities (e.g. hypospadias, congenital curvature, or Peyronie's disease with preserved rigidity) during the medical history and the physical examination is mandatory.

Blood pressure and heart rate should be measured if they have not been assessed in the previous three to six months. Likewise either a BMI calculation or waist circumference measurement should be undertaken to assess patients for comorbid conditions (e.g. MetS).

*5.4.3 **Laboratory testing***

Laboratory testing must be tailored to the patient's complaints and risk factors. Patients should undergo a fasting blood glucose or HbA1c and lipid profile if they have not been assessed in the previous twelve months. Hormonal tests should include an early morning total testosterone in a fasting state. The bio-available or calculated-free testosterone values may be sometimes needed to corroborate total testosterone measurements. However, the threshold of testosterone required to maintain an erection is low and ED is usually a symptom of more severe cases of hypogonadism (see sections 3.5 and 3.6) [20, 51, 294, 379, 380]. Additional laboratory tests may be considered in selected patients with specific signs and associated symptoms (e.g., PSA) [381]; prolactin, and LH [382]). Although physical examination and laboratory evaluation of most men with ED may not reveal the exact diagnosis, clinical and biochemical evaluation presents an opportunity to identify comorbid conditions [378].

Figure 3: Minimal diagnostic evaluation (basic work-up) in patients with ED



ED = erectile dysfunction; IIEF = International Index of Erectile Function.

*5.4.4 **Cardiovascular system and sexual activity: the patient at risk***

Patients who seek treatment for sexual dysfunction have a high prevalence of CVDs. Epidemiological surveys have emphasised the association between cardiovascular/metabolic risk factors and sexual dysfunction in both men and women [383]. Overall, ED can improve the sensitivity of screening for asymptomatic CVD in men with

diabetes [384, 385]. Erectile dysfunction significantly increases the risk of CVD, coronary heart disease and stroke. All of these cause mortality and the increase is probably independent of conventional cardiovascular risk factors [289, 290, 386, 387]. Longitudinal data from an observational population-based study of 965 men without CVD showed that younger men (especially those < 50 years) with transient and persistent ED have an increased Framingham CVD risk [388].

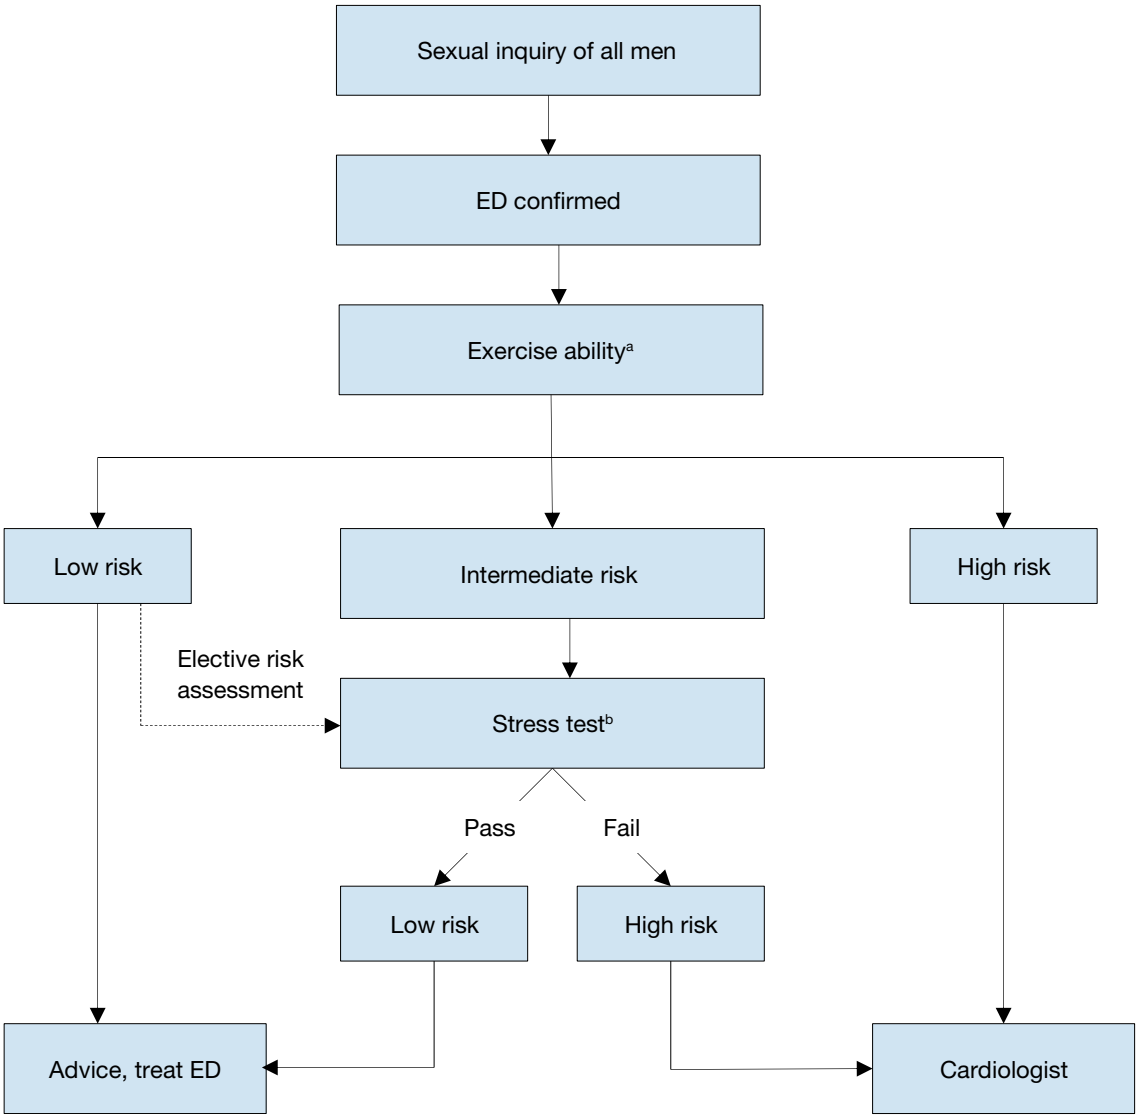
The EAU Guidelines for diagnosing and treating men with ED have been adapted from previously published recommendations from the Princeton Consensus conferences on sexual dysfunction and cardiac risk [389]. The Princeton Consensus (Expert Panel) Conference is dedicated to optimising sexual function and preserving cardiovascular health [389-391]. Accordingly, patients with ED can be stratified into three cardiovascular risk categories (Table 11), which can be used as the basis for a treatment algorithm for initiating or resuming sexual activity (Figure 3). It is also possible for the clinician to estimate the risk of sexual activity in most patients from their level of exercise tolerance, which can be determined when taking the patient's history [312].

Table 11: Cardiac risk stratification (based on 2nd and 3rd Princeton Consensus) [389, 391]

Low-risk category	Intermediate-risk category	High-risk category
Asymptomatic, < 3 risk factors for CAD (excluding sex)	≥ 3 risk factors for CAD (excluding sex)	High-risk arrhythmias
Mild, stable angina (evaluated and/or being treated)	Moderate, stable angina	Unstable or refractory angina
Uncomplicated previous MI	Recent MI (> 2, < 6 weeks)	Recent MI (< 2 weeks)
LVD/CHF (NYHA class I or II)	LVD/CHF (NYHA class III)	LVD/CHF (NYHA class IV)
Post-successful coronary revascularisation	Non-cardiac sequelae of atherosclerotic disease (e.g., stroke, peripheral vascular disease)	Hypertrophic obstructive and other cardiomyopathies
Controlled hypertension		Uncontrolled hypertension
Mild valvular disease		Moderate-to-severe valvular disease

CAD = coronary artery disease; CHF = congestive heart failure; LVD = left ventricular dysfunction; MI = myocardial infarction; NYHA = New York Heart Association.

Figure 4: Treatment algorithm for determining level of sexual activity according to cardiac risk in ED (based on 3rd Princeton Consensus) [389]



[a] *Sexual activity is equivalent to walking 1 mile on the flat in 20 minutes or briskly climbing two flights of stairs in 10 seconds.*

[b] *Sexual activity is equivalent to four minutes of the Bruce treadmill protocol.*

5.4.4.1 Low-risk category

The low-risk category includes patients who do not have any significant cardiac risk associated with sexual activity. Low-risk is typically implied by the ability to perform exercise of modest intensity, which is defined as, ≥ 6 metabolic equivalents of energy expenditure in the resting state without symptoms. According to current knowledge of the exercise demand or emotional stress associated with sexual activity, low-risk patients do not need cardiac testing or evaluation before the initiation or resumption of sexual activity or therapy for sexual dysfunction.

5.4.4.2 Intermediate- or indeterminate-risk category

The intermediate- or indeterminate-risk category consists of patients with an uncertain cardiac condition or patients whose risk profile requires testing or evaluation before the resumption of sexual activity. Based upon the results of testing, these patients may be moved to either the high- or low-risk group. A cardiology consultation may be needed in some patients to help the primary physician determine the safety of sexual activity.

5.4.4.3 High-risk category

High-risk patients have a cardiac condition that is sufficiently severe and/or unstable for sexual activity to carry a significant risk. Most high-risk patients have moderate-to-severe symptomatic heart disease. High-risk

individuals should be referred for cardiac assessment and treatment. Sexual activity should be stopped until the patient's cardiac condition has been stabilised by treatment, or a decision made by the cardiologist and/or internist that it is safe to resume sexual activity.

5.5 Diagnostic Evaluation (advanced work-up)

Most patients with ED can be managed based on the basis of medical and sexual history; conversely, some patients may need specific diagnostic tests (Tables 12 and 13).

*5.5.1 **Nocturnal penile tumescence and rigidity test***

The nocturnal penile tumescence and rigidity (NPTR) test applies nocturnal monitoring devices that measure the number of erectile episodes, tumescence (circumference change by strain gauges), maximal penile rigidity, and duration of nocturnal erection(s). The NPTR assessment should be performed on at least two separate nights. A functional erectile mechanism is indicated by an erectile event of at least 60% rigidity recorded on the tip of the penis that lasts for ten or more minutes [392]. Nocturnal penile tumescence and rigidity monitoring is an attractive approach for objectively differentiating between organic and psychogenic ED (patients with psychogenic ED usually have normal findings in the NPTR test). However, many potential confounding factors (e.g., situational) may limit its routine use for diagnostic purposes [393].

*5.5.2 **Intracavernous injection test***

The intracavernous injection test gives limited information about the vascular status. A positive test is a rigid erectile response (unable to bend the penis) that appears within ten minutes after the intracavernous injection and lasts for 30 minutes [394]. Overall, the test is inconclusive as a diagnostic procedure and a duplex Doppler study of the penis should be requested, if clinically warranted.

*5.5.3 **Dynamic duplex ultrasound of the penis***

Dynamic duplex ultrasound (US) of the penis is a second-level diagnostic test specifically aimed to study the haemodynamic pathophysiology of erectile function. Therefore in clinical practice it is usually applied in those conditions where a potential vasculogenic aetiology of ED (e.g., diabetes mellitus; renal transplantation; multiple concomitant CV risk factors and/or overt peripheral vascular disease; poor responders to oral therapy, etc.) is suspected. A peak systolic blood flow > 30 cm/s, an end-diastolic velocity of < 3 cm/s and a resistance index > 0.8 are generally considered normal [395, 396]. Recent data have suggested that duplex scanning as a haemodynamic study may be better at tailoring therapy for ED, such as for low-intensity shock wave (LI-SWT) treatment and for diagnosing vasculogenic ED [397]. Further vascular investigation is unnecessary if a duplex US examination is normal.

*5.5.4 **Arteriography and dynamic infusion cavernosometry or cavernosography***

Pudendal arteriography should be performed only in patients who are being considered for penile revascularisation [398]. Recent studies have advocated the use of computerised tomography (CT) angiography as a diagnostic procedure prior to penile artery angioplasty for patients with ED and isolated penile artery stenosis [399]. Nowadays, dynamic infusion cavernosometry or cavernosography are infrequently used diagnostics tools aimed at diagnosing venogenic ED.

*5.5.5 **Psychiatric and psychosocial assessment***

Whenever clinically indicated, patients with psychiatric disorders should be referred to a psychiatrist. In younger patients (< 40 years) with long-term primary ED [170], psychiatric assessment may be helpful before any clinical assessment is carried out.

Mental health issues are frequently comorbid with ED; this is most evident for depression and anxiety related disorders, but may also include transitory states of altered mood (i.e., dysfunctional affective states resulting from a specific life stressor) [307, 400]. Relationship factors, including lack of satisfaction with the partner, poor sexual relationships, length of the relationship, or feeling emotionally disconnected with the partner during sex, have been related to erectile difficulties and dysfunction [400-402]. On the other hand, feeling emotionally supported, and motivated toward intimacy are protective factors in men with ED [403]. Additionally, the cognitive factors underpinning organic and non-organic ED must also be assessed. Cognitive factors include men's dysfunctional thinking styles and expectations about sexuality and sexual performance. These expectations result from the sexuality norms and stereotypes, shared by a given culture. Expectations emphasising high sexual performance in men, result in sexual performance anxiety, acting as a maintenance factor of ED [404]. Unrealistic expectations about male sexual performance may further align with internal causal attributions regarding the loss of erection (i.e., men attribute the loss of erection to themselves [sense of personal inadequacy]), thereby worsening ED [405]. Likewise, poor self-esteem and cognitive distraction from erotic cues, are expected to negatively impact ED [406, 407].

Psychosexual assessment in ED cases include a clinical interview considering all the previous topics; clinicians are expected to collect information on the individual's psychopathology symptoms, life stressors, relationship dynamics, cognitive style, and cognitive distraction sources [406]. Also, self-reported measures are frequently used within the psychological context. These may include measurement scales such as the Brief Symptom Inventory [408] for measuring psychopathology symptoms, the Sexual Dysfunctional Beliefs Questionnaire [409] or the Sexual Modes Questionnaire [410] for measuring dysfunctional cognitive styles in men.

Figure 5: Psychiatric and psychosocial assessment

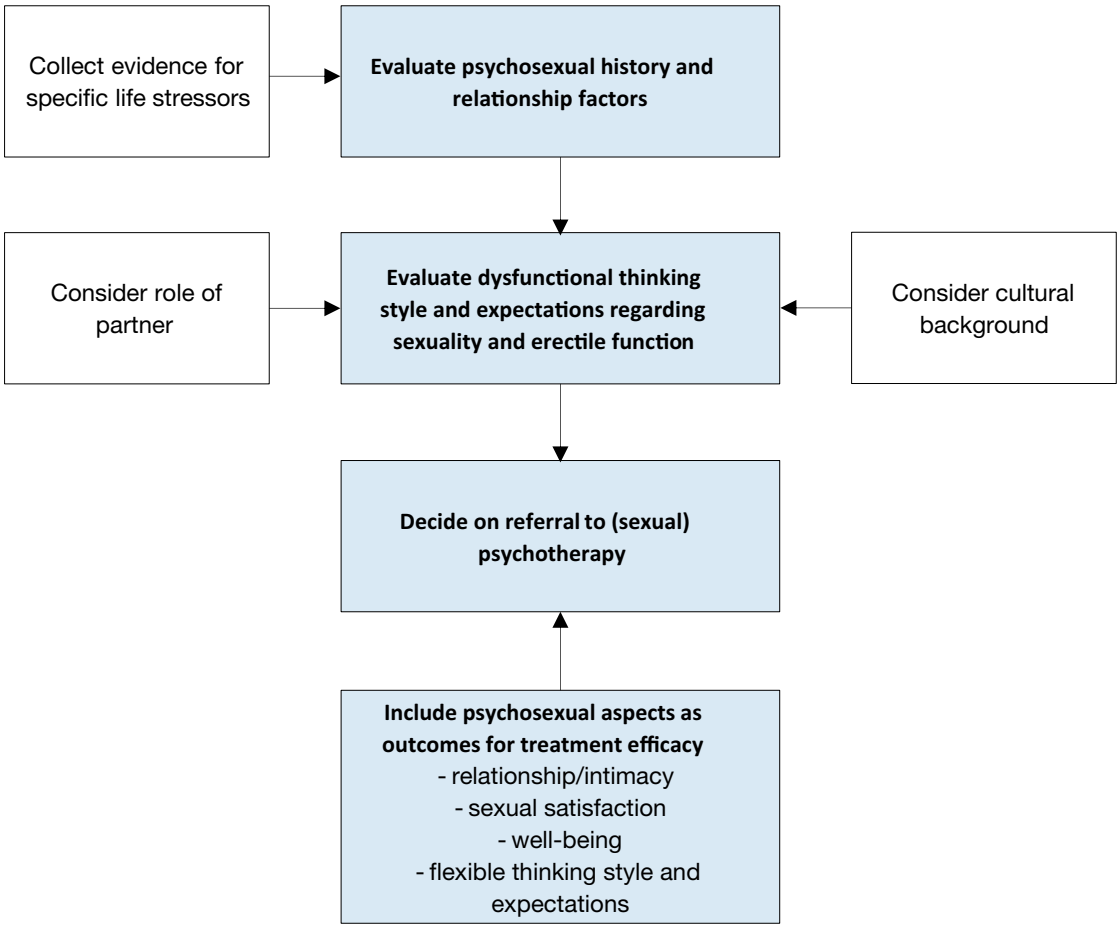


Table 12: Indications for specific diagnostic tests for ED

Primary ED (not caused by acquired organic disease or psychogenic disorder).
Young patients with a history of pelvic or perineal trauma, who could benefit from potentially curative revascularisation surgery or angioplasty.
Patients with penile deformities which might require surgical correction (e.g., Peyronie's disease, congenital penile curvature).
Patients with complex psychiatric or psychosexual disorders.
Patients with complex endocrine disorders.
Specific tests may be indicated at the request of the patient or their partner.
Medico-legal reasons (e.g., implantation of penile prosthesis to document end stage ED, sexual abuse).

Table 13: Specific diagnostic tests for ED

Nocturnal Penile Tumescence and Rigidity (NTPR) using Rigiscan®
Vascular studies - Intracavernous vasoactive drug injection - Penile dynamic duplex ultrasonography - Penile dynamic infusion cavernosometry and cavernosography - Internal pudendal arteriography
Specialised endocrinological studies
Specialised psychodiagnostic evaluation

*5.5.6 **Recommendations for the diagnostic evaluation of ED***

Recommendations	Strength rating
Take a comprehensive medical and sexual history in every patient presenting for erectile dysfunction (ED). Consider psychosexual development, including life stressors, cultural aspects, and cognitive/thinking style of the patient regarding their sexual performance.	Strong
Use a validated questionnaire related to ED to assess all sexual function domains (e.g., International Index of Erectile Function) and the effect of a specific treatment modality.	Strong
Include a focused physical examination in the initial assessment of men with ED to identify underlying medical conditions and comorbid genital disorders that may be associated with ED.	Strong
Assess routine laboratory tests, including glucose and lipid profile and total testosterone, to identify and treat any reversible risk factors and lifestyle factors that can be modified.	Strong
Include specific diagnostic tests in the initial evaluation of ED in the presence of the conditions presented in Table 11.	Strong

5.6 Treatment of erectile dysfunction

*5.6.1 **Patient education - consultation and referrals***

Educational intervention is often the first approach to sexual complaints, and consists of informing patients about the psychological and physiological processes involved in the individual's sexual response, in ways he can understand. This first level approach was shown to favour sexual satisfaction in ED men [411]. Accordingly, consultation with the patient should include firstly a discussion of the expectations and needs of both the patient and their sexual partner. It should also review both the patient and partner's understanding of ED and the results of diagnostic tests, and provide a rational for the selection of treatment options [412]. Patient and partner education is an essential part of ED management [412, 413], and may prevent misleading information that may be at the core of dysfunctional psychological processes underpinning ED.

*5.6.2 **Treatment options***

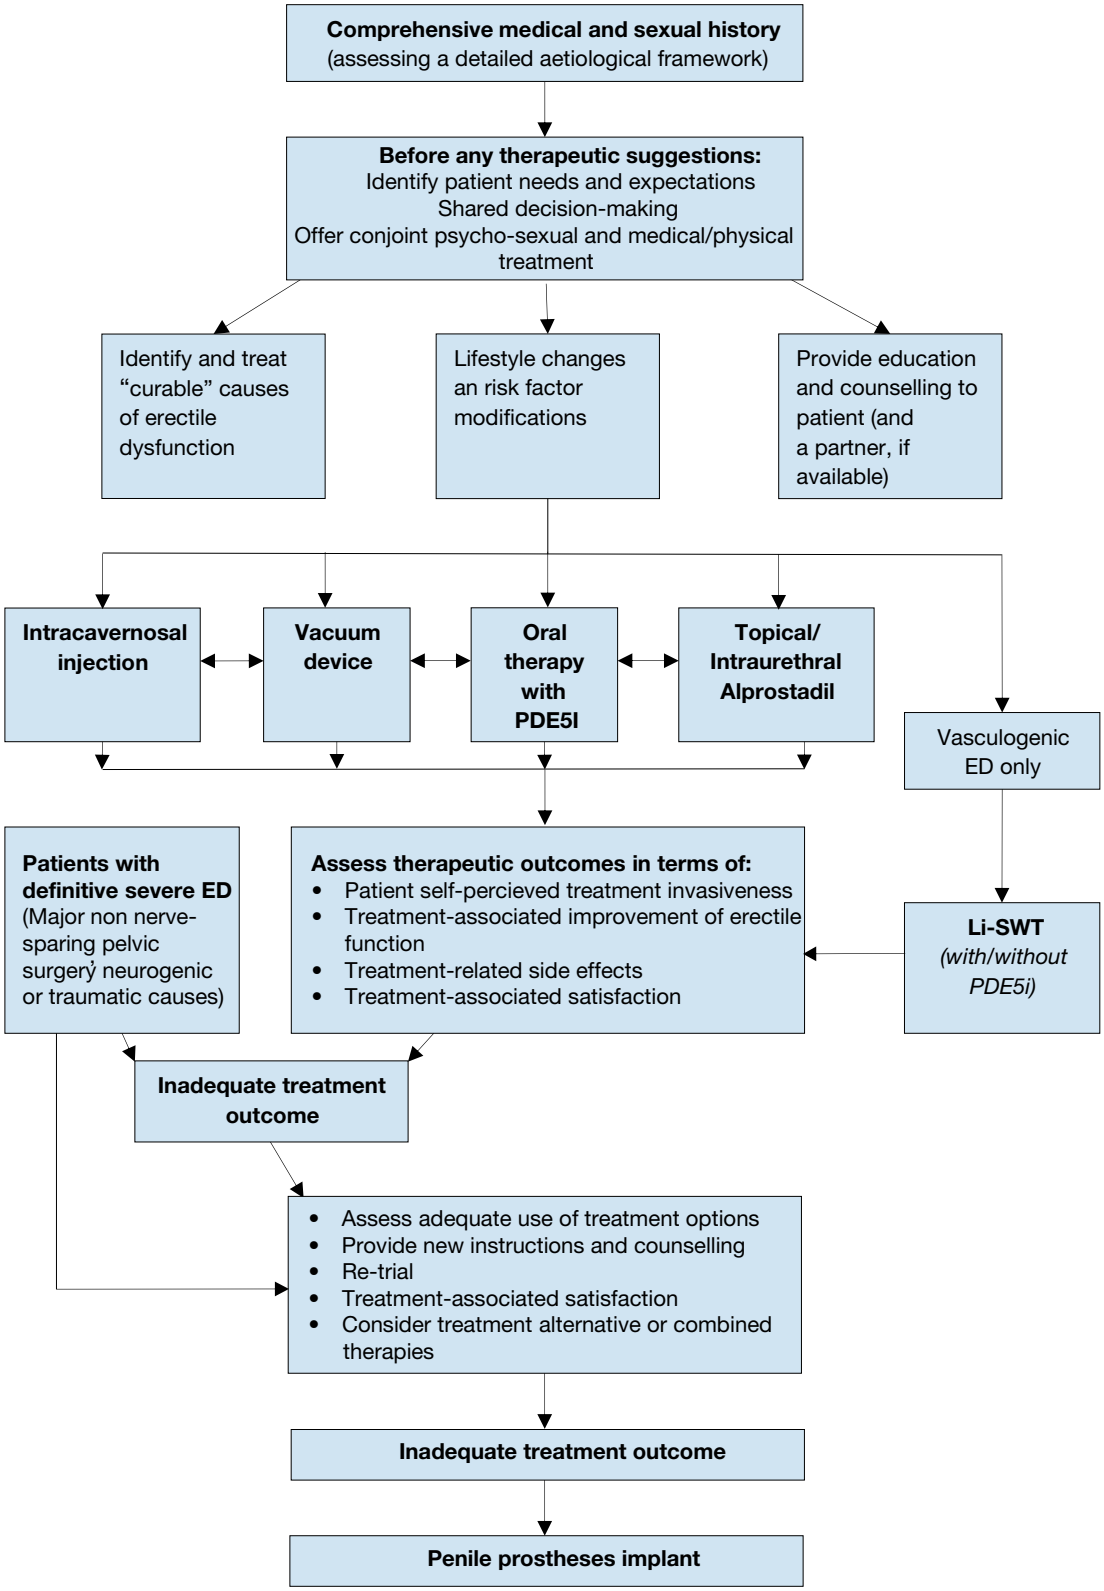
Based on the currently available evidence and the consensus of the panel, a novel comprehensive therapeutic and decision-making algorithm (Figure 6) for treating ED, which takes into account both the level of invasiveness of each therapy and the efficacy of the therapy itself, is presented. This newly-developed treatment algorithm has been extensively discussed within the guidelines panel as an alternative to the traditional three-level concept in order to better tailor a personalised therapy to individual patients, according to invasiveness, tolerability, effectiveness of the different therapeutic options and patients' expectations. In this context, patients should be fully counselled with respect to all available treatment modalities.

Erectile dysfunction may be associated with modifiable or reversible risk factors, including lifestyle or drug-related factors [308]. These factors may be modified either before, or at the same time as, specific therapies are used. Likewise, ED may be associated with concomitant and underlying conditions (such as, endocrine disorders and metabolic disorders - e.g., diabetes - some cardiovascular problems - e.g., hypertension) which should always be well-controlled as the first step of any ED treatment [414]. Major clinical potential benefits of lifestyle changes may be achieved in men with specific comorbid cardiovascular or metabolic disorders, such as diabetes or hypertension [308, 415].

As a rule, ED can be treated successfully with current treatment options, but it cannot be cured. The only exceptions are psychogenic ED, post-traumatic arteriogenic ED in young patients, and hormonal causes (e.g., hypogonadism) [51, 382], which potentially can be cured with specific treatments. Most men with ED

will be treated with therapeutic options that are not cause specific. This results in a tailored treatment strategy that depends on invasiveness, efficacy, safety, and cost, as well as patient preference [412]. In this context, physician-patient (partner, if available) dialogue is essential throughout the management of ED.

Figure 6: Management algorithm for erectile dysfunction



ED = erectile dysfunction; PDE5Is = phosphodiesterase type 5 inhibitors.

5.6.2.1 Oral pharmacotherapy

Four potent selective PDE5Is have been approved by the EMA for the treatment of ED [416]. Phosphodiesterase type 5 catalyses the hydrolysis of the second messenger cyclic guanosine monophosphate (cGMP) in the cavernous tissue; cGMP is involved in intra-cellular signal pathways of cavernous smooth muscle. Indeed, the accumulation of cGMP sets in motion a cascade of events at the intracellular level, which induces a loss of contractile tone of the vessels at the penile level by lowering cytosolic Ca^{2+}. Nitric oxide (NO) has an essential role in promoting the formation of cGMP and other pathways leading to corporeal smooth muscle relaxation and erection of the penis [414, 417]. This is associated with increased arterial blood flow, eventually leading to compression of the sub-tunical venous plexus followed by penile erection [418]. Since they are not initiators of erection, PDE5Is require sexual stimulation to facilitate an erection. Efficacy is defined as an erection, with rigidity, sufficient for satisfactory intercourse [414].

Sildenafil

Sildenafil was launched in 1998 and was the first PDE5I available on the market [419]. It is administered in doses of 25, 50 and 100 mg. The recommended starting dose is 50 mg and should be adapted according to the patient's response and side-effects [419]. Sildenafil is effective 30-60 minutes after administration [419]. Its efficacy is reduced after a heavy, fatty meal due to delayed absorption. Efficacy may be maintained for up to twelve hours [420]. The pharmacokinetic profile for sildenafil is presented in Table 14. Adverse events (Table 15) are generally mild in nature and self-limited [421, 422]. After 24 weeks in a dose-response study, improved erections were reported by 56%, 77% and 84% in a general ED population taking 25, 50 and 100 mg sildenafil, respectively, compared to 25% of men taking placebo [423]. Sildenafil significantly improved patient scores for IIEF, Sexual Encounter Profile (SEP)2, SEP3, and General Assessment Questionnaire (GAQ) and treatment satisfaction. The efficacy of sildenafil in almost every subgroup of patients with ED has been successfully established, irrespective of age [424]. Recently, an orally disintegrating tablet (ODT) of sildenafil citrate at a dosage of 50 mg has been developed mainly for the benefit of patients who have difficulty swallowing solid dosage forms.

Tadalafil

Tadalafil was licensed for treatment of ED in February 2003 and is effective from 30 minutes after administration, with peak efficacy after about two hours [425]. Efficacy is maintained for up to 36 hours [425] and is not affected by food [426]. Usually, it is administered in on-demand doses of 10 and 20 mg or a daily dose of 5 mg. The recommended on-demand starting dose is 10 mg and should be adapted according to the patient's response and side-effects [425, 427]. Pharmacokinetic data for tadalafil is presented in Table 14. Adverse events (Table 15) are generally mild in nature and self-limited by continuous use. In pre-marketing studies, after twelve weeks of treatment in a dose-response study, improved erections were reported by 67% and 81% of a general ED population taking 10 and 20 mg tadalafil, respectively, compared to 35% of men in the control placebo group [425]. Tadalafil significantly improved patient scores for IIEF, SEP2, SEP3, and GAQ and treatment satisfaction [425].

Efficacy has been confirmed in post-marketing studies [416, 428]. The efficacy of tadalafil in almost every subgroup of patients with ED, including difficult-to-treat subgroups (e.g., diabetes mellitus), has been successfully established [429], in addition to the evidence of a net clinical advantage in the short-term on ejaculatory and orgasmic functions in ED patients [430]. Daily tadalafil has also been licensed for the treatment of LUTS secondary to BPH. Therefore, it is useful in patients with concomitant ED and LUTS [431]. Recent data also confirms that 40% of men aged > 45 years were combined responders for ED and LUTS/BPH to treatment with tadalafil 5 mg once daily, with symptom improvement after twelve weeks [432].

Vardenafil

Vardenafil became commercially available in March 2003 and is effective from 30 minutes after administration [433], with up to one out of three patients achieving satisfactory erections within 15 minutes of ingestion [434]. Its effect is reduced by a heavy, fatty meal. Doses of 5, 10 and 20 mg have been approved for on-demand treatment of ED. The recommended starting dose is 10 mg and should be adapted according to the patient's response and side-effects [435]. Pharmacokinetic data for vardenafil is presented in Table 14. Adverse events (Table 15) are generally mild in nature and self-limited by continuous use [435]. After twelve weeks in a dose-response study, improved erections were reported by 66%, 76% and 80% of a general ED population taking 5, 10 and 20 mg vardenafil, respectively, compared with 30% of men taking placebo [435, 436]. Vardenafil significantly improved patient scores for IIEF, SEP2, SEP3, and GAQ and treatment satisfaction.

Efficacy has been confirmed in post-marketing studies [435, 436]. The efficacy of vardenafil in almost every subgroup of patients with ED, including difficult-to-treat subgroups (e.g. diabetes mellitus), has been successfully established. More recently, an ODT form of vardenafil has been released [436]. Orodispersable tablet formulations offer improved convenience over film-coated formulations and may be

preferred by patients. Absorption is unrelated to food intake and they exhibit better bio-availability compared to film-coated tablets [437]. The efficacy of vardenafil ODT has been demonstrated in several RCTs and did not seem to differ from the regular formulation [437-439].

Avanafil

Avanafil is a highly-selective PDE5I that became commercially available in 2013 [440]. Avanafil has a high ratio of inhibiting PDE5 as compared with other PDE subtypes, ideally allowing for the drug to be used for ED while minimising adverse effects (although head-to-head comparison studies are not yet available) [441]. Doses of 50 mg, 100 mg, and 200 mg have been approved for on-demand treatment of ED [440]. The recommended starting dose is 100 mg taken as needed approximately 15 to 30 minutes before sexual activity and the dosage may be adapted according to efficacy and tolerability [440, 442, 443]. In the general population with ED, the mean percentage of attempts resulting in successful intercourse was approximately 47%, 58%, and 59% for the 50 mg, 100 mg, and 200 mg avanafil groups, respectively, as compared with approximately 28% for placebo [440, 442]. Data from sexual attempts made within fifteen minutes of dosing showed successful attempts in 64%, 67%, and 71% of cases, with avanafil 50, 100, and 200 mg, respectively. Dosage adjustments are not warranted based on renal function, hepatic function, age or gender [442]. Pharmacokinetic data for avanafil is presented in Table 14 [440, 442]. Adverse events are generally mild in nature (Table 15) [440, 442]. Pairwise meta-analytic data from available studies suggested that avanafil significantly improved patient scores for IIEF, SEP2, SEP3, and GAQ, with an evident dose-response relationship [440, 444]. Administration with food may delay the onset of effect compared with administration in a fasting state but avanafil can be taken with or without food [445]. The efficacy of avanafil in many groups of patients with ED, including difficult-to-treat subgroups (e.g., diabetes mellitus), has been successfully established. As for dosing, 36.4% (28 of 77) of sexual attempts (SEP3) at fifteen minutes or less were successful with avanafil versus 4.5% (2 of 44) after placebo ($p < 0.01$) [446]. A recent meta-analysis confirmed that avanafil had comparable efficacy with sildenafil, vardenafil and tadalafil treatments [445].

Choice or preference between the different PDE5Is

To date, no data are available from double- or triple-blind multicentre studies comparing the efficacy and/or patient preference for the most-widely available PDE5Is (i.e., sildenafil, tadalafil, vardenafil, and avanafil). Choice of drug will depend on the frequency of intercourse (occasional use or regular therapy, three to four times weekly) and the patient's personal experience. Patients need to know whether a drug is short- or long-acting, its possible disadvantages, and how to use it. A meta-analysis demonstrated that ED patients who prioritise high efficacy must use sildenafil 50 mg whereas those who optimise tolerability should initially use tadalafil 10 mg and switch to udenafil 100 mg if the treatment is not sufficient (however, udenafil 100 mg is not EMA or FDA approved and is not available in Europe) [428]. In addition, results of another clinical trial revealed that tadalafil 5 mg once daily may improve the erectile function outcomes among men who had a partial response to on-demand PDE5I therapy [447].

Continuous use of PDE5Is

Animal studies have shown that chronic use of PDE5Is significantly improves or prevents the intracavernous structural alterations due to age, diabetes, or surgical damage [448-452]. No data exists in humans. In humans, it has been clinically demonstrated that treatment with tadalafil 5 mg once-daily in men complaining of ED of various severities was well tolerated and effective [453]. In 2007, tadalafil 2.5 and 5 mg were approved by the EMA for daily treatment of ED. According to the EMA, a once-daily regimen with tadalafil 2.5 mg or 5 mg might be considered suitable, based on patient choice and the physician's judgement. In these patients, the recommended dose is 5 mg, taken once a day at approximately the same time. Overall, tadalafil, 5 mg once daily, provides an alternative to on-demand dosing of tadalafil for couples who prefer spontaneous rather than scheduled sexual activities or who anticipate frequent sexual activity, with the advantage that dosing and sexual activity no longer need to be linked. The appropriateness of the continuous use of a daily regimen should be re-assessed periodically [453, 454]. A recently published integrated analysis showed that no clinical populations of patients with ED seemed to benefit overwhelmingly from tadalafil once daily over on-demand dosing regimen and vice versa [455]. Furthermore, a recent RCT showed that there is no clinical benefit on endothelial dysfunction measured by flow-mediated dilation deriving from daily tadalafil when compared to placebo [456]. Although some authors reported improved erectile function when long-term tadalafil 5 mg once daily is combined with sildenafil as needed [457], more safety analyses are required to give a formal recommendation on such a therapy.

Table 14: Summary of the key pharmacokinetic data for the four PDE5Is currently EMA-approved to treat ED*

Parameter	Sildenafil, 100 mg	Tadalafil, 20 mg	Vardenafil, 20 mg	Avanafil, 200mg
C_{max}	560 µg/L	378 µg/L	18.7 µg/L	5.2 µg/L
T_{max} (median)	0.8-1 hours	2 hours	0.9 hours	0.5-0.75 hours
T1/2	2.6-3.7 hours	17.5 hours	3.9 hours	6-17 hours
AUC	1,685 µg.h/L	8,066 µg.h/L	56.8 µg.h/L	11.6 µg.h/L
Protein binding	96%	94%	94%	99%
Bioavailability	41%	NA	15%	8-10%

** Fasted state, higher recommended dose. Data adapted from EMA statements on product characteristics. C_{max} = maximal concentration; T_{max} = time-to-maximum plasma concentration; T1/2 = plasma elimination halftime; AUC = area under curve or serum concentration time curve.*

Table 15: Common adverse events of the four PDE5Is currently EMA-approved to treat ED*

Adverse event	Sildenafil	Tadalafil	Vardenafil	Avanafil, 200mg
Headache	12.8%	14.5%	16%	9.3%
Flushing	10.4%	4.1%	12%	3.7%
Dyspepsia	4.6%	12.3%	4%	uncommon
Nasalcongestion	1.1%	4.3%	10%	1.9%
Dizziness	1.2%	2.3%	2%	0.6%
Abnormalvision	1.9%		< 2%	None
Back pain		6.5%		< 2%
Myalgia		5.7%		< 2%

** Adapted from EMA statements on product characteristics.*

Safety issues for PDE5Is

- **Cardiovascular safety**

Clinical trial results for the four PDE5Is and post-marketing data of sildenafil, tadalafil, and vardenafil have demonstrated no increase in myocardial infarction rates in patients receiving PDE5Is, as part of either RCTs or open-label studies, or compared to expected rates in age-matched male populations. None of the PDE5Is had an adverse effect on total exercise time or time-to-ischaemia during exercise testing in men with stable angina [416, 458]. Chronic or on-demand use is well tolerated with a similar safety profile. The prescription of all PDE5Is in patients with CVD or in those with high CV risk should be based on the recommendations of the 3rd Princeton Consensus Panel [389].

- **Contraindication for the concomitant use of organic nitrates**

Absolute contraindication to PDE5Is is represented by patients who are using any form of organic nitrate (e.g., nitroglycerine, isosorbide mononitrate, and isosorbide dinitrate) or NO donors (e.g., other nitrate preparations used to treat angina, as well as amyl nitrite or amyl nitrate such as “poppers” which are used for recreation). They result in cGMP accumulation and unpredictable falls in blood pressure and symptoms of hypotension. The duration of interaction between organic nitrates and PDE5Is depends upon the PDE5I and nitrate used. If a PDE5I is taken and the patient develops chest pain, nitroglycerine must be withheld for at least 24 hours if sildenafil (and probably also vardenafil) is used (half-life, four hours), or at least 48 hours if tadalafil is used (half-life, 17.5 hours), and for no less than twelve hours if avanafil is used (half-life, 6-17 hours) [459-462].

- **Use caution with antihypertensive drugs**

Co-administration of PDE5Is with antihypertensive agents (angiotensin-converting enzyme inhibitors, angiotensin-receptor blockers, calcium blockers, β-blockers, and diuretics) may result in small additive decreases in blood pressure, which are usually minor [389]. In general, the adverse event profile of a PDE5I is not worsened by a background of antihypertensive medication, even when the patient is taking several antihypertensive agents [463].

- **Interaction with Nicorandil**

In vitro studies in animals suggest that the potassium channel opener nicorandil may potentiate the vasorelaxation induced by isoproterenol in isolated rat aorta by increasing cyclic GMP levels [464]. This may be due to the nitric oxide donating properties of nicorandil. Therefore the concurrent use of nicorandil and PDE5Is is also contraindicated.

α-Blocker interactions

All PDE5Is show some interaction with α-blockers, which under some conditions may result in orthostatic hypotension.

- Sildenafil labelling advises that 50 or 100 mg sildenafil should be used with caution in patients taking an α-blocker (especially doxazosin). Hypotension is more likely to occur within four hours following treatment with an α-blocker. A starting dose of 25 mg is recommended [421].
- Concomitant treatment with vardenafil should only be initiated if the patient has been stabilised on their α-blocker therapy. Co-administration of vardenafil with tamsulosin is not associated with clinically significant hypotension [433, 435, 436].
- Tadalafil is not recommended in patients taking doxazosin, but this is not the case for tamsulosin [425, 465].
- Avanafil labelling currently reports that patients should be stable on α-blocker therapy prior to initiating avanafil. In these patients, avanafil should be initiated at the lowest dose of 50 mg. Conversely, in those patients already taking an optimised dose of avanafil, α-blocker therapy should be initiated at the lowest dose.

In the everyday clinical practice, a patient presenting for ED should be stable on one medication (every α-blocker except for doxazosin which should be avoided whenever possible) before starting a PDE5Is.

Dosage adjustment

Drugs that inhibit the CYP34A pathway will inhibit the metabolic breakdown of PDE5Is, thus increasing PDE5Is blood levels (e.g. ketoconazole, ritonavir, atazanavir, clarithromycin, indinavir, itraconazole, nefazodone, nelfinavir, saquinavir and telithromycin). Therefore, lower doses of PDE5Is are necessary. However, other agents, such as rifampin, phenobarbital, phenytoin and carbamazepine, may induce CYP3A4 and enhance the breakdown of PDE5Is, so that higher doses of PDE5Is are required. Severe kidney or hepatic dysfunction may require dose adjustments or warnings.

Management of non-responders to PDE5Is

The two main reasons why patients fail to respond to a PDE5I are either incorrect drug use or lack of efficacy of the drug. Data suggest that an adequate trial involves at least six attempts with a particular drug [466]. The management of non-responders depends upon identifying the underlying cause [467]. Check that the patient has been using a licensed medication. There is a large counterfeit market in PDE5Is. The amount of active drug in these medications varies enormously and it is important to check how and from which source the patient has obtained his medication.

Check that the medication has been properly prescribed and correctly used. The main reason why patients fail to use their medication correctly is inadequate counselling from their physician. The most common causes of incorrect drug use are: i) failure to use adequate sexual stimulation; ii) failure to use an adequate dose; and, iii) failure to wait an adequate amount of time between taking the medication and attempting sexual intercourse.

PDE5I action is dependent on the release of NO by the parasympathetic nerve endings in the erectile tissue of the penis. The usual stimulus for NO release is sexual stimulation, and without adequate sexual stimulation (and NO release), the medication is ineffective. Oral PDE5Is take different times to reach maximal plasma concentrations [420, 422, 437, 444, 468-470]. Although pharmacological activity is achieved at plasma levels well below the maximal plasma concentration, there will be a period of time following oral ingestion of the medication during which the drug is ineffective. Even though all four drugs have an onset of action in some patients within 15-30 minutes of oral ingestion [422, 437, 468-470], most patients require a longer delay between taking the medication [435, 444, 471, 472]. Absorption of both sildenafil and vardenafil can be delayed by a heavy, fatty meal [473]. Absorption of tadalafil is less affected, and food has negligible effects on its bioavailability [468]. When avanafil is taken with a high fat meal, the rate of absorption is reduced with a mean delay in T_{max} of 1.25 hours and a mean reduction in C_{max} of 39% (200 mg). There is no effect on the extent of exposure (AUC). The small changes in avanafil C_{max} are considered to be of minimal clinical significance [440, 441, 444].

It is possible to wait too long after taking the medication before attempting sexual intercourse. The half-life of sildenafil and vardenafil is about four hours, suggesting that the normal window of efficacy is six to eight hours following drug ingestion, although responses following this time period are well recognised. The half-life of avanafil is six to seventeen hours. Tadalafil has a longer half-life of ~17.5 hours, so the window of efficacy is much longer at ~36 hours. Data from uncontrolled studies suggest patient education can help salvage an apparent non-responder to a PDE5I [467, 474-477]. After emphasising the importance of dose, timing, and sexual stimulation to the patient, erectile function can be effectively restored following re-administration of the relevant PDE5I [467, 474, 475].

Recent data suggested that response to sildenafil treatment was also dependent on polymorphism in the PDE5A gene, which encodes the principal cGMP-catalysing enzyme in the penis, regulating cGMP clearance, and it is the primary target of sildenafil [478-480].

Clinical strategies in patients correctly using a PDE5Is

Overall, treatment goals should be individualised to restore sexual satisfaction for the patient and/or couple and improve QoL based on the patient's expressed needs and desires [481]. In this context, data suggests that almost half of patients abandon first-generation PDE5Is within one year, with no single specific factor playing a major role in PDE5Is dropout rates [482].

Uncontrolled trials have demonstrated that hypogonadal patients not responding to PDE5Is may improve their response to PDE5Is after initiating testosterone therapy [51, 414, 483]. Therefore, in the real-life setting most patients with ED will first be prescribed a PDE5I, which is usually effective; however, if diagnostic criteria suggestive for testosterone deficiency are present, testosterone replacement therapy may be a more appropriate treatment even in ED patients [5, 51].

Modification of other risk factors may also be beneficial as previously discussed. Limited data suggest that some patients might respond better to one PDE5I than to another [484] and although these differences might be explained by variations in drug pharmacokinetics, they do raise the possibility that, despite an identical mode of action, switching to a different PDE5I might be helpful. However it is important to emphasise that the very few randomised studies show any difference in clinical outcomes with different drugs and intake patterns both in patients with classic ED [485] and in special populations such as diabetics [486].

Moreover, in patients with severe ED, it has been suggested to combine tadalafil daily dosing with a short acting PDE5I (such as sildenafil), without any significant increase in terms of side-effects [457]; robust prospective data from RCTs to support combination treatments with any oral preparations are still lacking and should therefore be used with caution. If drug treatment fails, then patients can be offered an alternative therapy such as intracavernous injection therapy or use of a vacuum erection device (VED). Likewise, limited data suggest the combination of a PDE5I with alprostadil as intracavernosal, intraurethral or topical application in patients who have previously failed therapy with either drug [487]. Review findings indicated that with all three formulations the combination therapy resulted in an improved outcome compared with either of the drugs as monotherapy, even for patients with post-prostatectomy ED. Treatment-emergent side-effects of the combined treatment did not result in treatment discontinuation [487].

5.6.2.2 Topical/Intraurethral alprostadil

The vasoactive agent alprostadil can be administered per urethra with two different formulations. The first compound is the topical route using a cream that includes a permeation enhancer in order to facilitate absorption of alprostadil (200 and 300 µg) via the urethral meatus [488, 489]. Clinical data are still limited. Significant improvement compared to placebo was recorded for IIEF-EF domain score, SEP2 and SEP3 in a broad range of patients with mild-to-severe ED [490]. Side-effects include penile erythema, penile burning and pain that usually resolves within two hours of application. Systemic side effects are very rare. Topical alprostadil (VITAROSTM) at the dose of 300 µg is currently approved and it is available in some European countries. Recently a randomised cross-over clinical trial showed that, compared to the standard administration route, the direct delivery of the drug within the urethral meatus is able to increase the level of treatment efficacy and confidence among patients, without increasing the incidence of side-effects [491].

The second method of delivery is by the intra-urethral insertion of a specific formulation of alprostadil (125-1000 µg) in a medicated pellet (MUSE™) [229]. Erections sufficient for intercourse are achieved in 30-65.9% of patients. In clinical practice, it is recommended that intra-urethral alprostadil be initiated at a dose of 500 µg, as it has a higher efficacy than the 250 µg dose, with minimal differences with regard to adverse events. In case of unsatisfactory clinical response the dose can be increased to 1000 µg [492-494]. The application of a constriction ring at the root of the penis may improve efficacy [493, 494].

Overall, the most common adverse events are local pain (29-41%) and dizziness with possible hypotension (1.9-14%). Penile fibrosis and priapism are very rare (< 1%). Urethral bleeding (5%) and urinary tract infections (0.2%) are adverse events related to the mode of administration. Efficacy rates are significantly lower than intracavernous pharmacotherapy [495], with a ~30% of adherence to long-term therapy. Intraurethral pharmacotherapy provides an alternative to intracavernous injections in patients who prefer a less-invasive, although less-efficacious treatment.

5.6.2.3 Shockwave therapy

The use of l LI-SWT has been increasingly proposed as a treatment for vasculogenic ED over the last decade, being the only currently marketed treatment that might offer a cure, which is the most desired outcome for most men suffering from ED [397, 496-503].

Overall, several single-arm trials have shown benefit of LI-SWT on patient-reported erectile function scores, but data from prospective randomised trials are conflicting, and many questions remain to be answered especially because of the variation in shockwave generators (electrohydraulic, electromagnetic, piezoelectric, electropneumatic), type of shockwaves delivered (focused, linear, semi-focused, unfocused), set-up parameters (energy flux density and number of pulses per session) and treatment protocols (duration of treatment course, number of sessions per week, total number of shockwaves pulses delivered, penile sites of application) [504]. As a whole, most of the studies suggest that LI-SWT can significantly increase the IIEF and Erection Hardness Score in patients with mild vasculogenic ED, rather than improve penile hemodynamic parameters [504, 505]. Likewise, data suggest that LI-SWT could ameliorate erection quality even in patients with severe ED who are PDE5Is non-responders [501, 506] or inadequate responders [507], reducing the immediate need for more invasive treatments. However, prospective RCTs and longer-term follow-up data would provide the clinician with more confidence regarding the use and efficacy of LI-SWT for ED. Further clarity is also needed in defining treatment protocols that can result in greater clinical benefits [508, 509].
Overall, according to the available data and the novel treatment decision algorithm, patients with vasculogenic ED may be treated with LI-SWT, although they should be fully counselled before treatment.

5.6.2.4 Psychosexual counselling and therapy

For patients with a recognised psychological problems [510], psychosexual therapy may be given either alone or with another therapeutic approach in order to improve couple's sexual satisfaction and partner's sexual function [511]. Psychosexual therapy requires ongoing follow-up and has had variable results [512]. Despite this psychological treatments including different modalities (e.g., sexual skills training, marital therapy, psychosexual education) [411], Cognitive and Behaviour Therapy (CBT), including group or couple format, has been recommended [406]. Cognitive and behaviour therapy is aimed at altering dysfunctional cognitive and behavioural patterns influencing ED, and increasing adjustment during the course of the disorder. Some of its techniques include identifying triggers preceding erectile difficulties, cognitive restructuring of dysfunctional thinking styles, learning coping skills aimed at dealing with erectile difficulties and emotional symptoms, and relapse prevention. The CBT approach combined with the medical treatment for ED has received empirical support and is considered an optimal procedure [406].

5.6.2.5 Hormonal treatment

The advice of an endocrinologist should be sought for managing patients with hormonal abnormalities or endocrinopathies [382]. Testosterone deficiency is either a result of primary testicular failure or secondary to pituitary/hypothalamic causes (e.g., a functional pituitary tumour resulting in hyperprolactinaemia) [382, 513]. When clinically indicated [514], testosterone replacement therapy (intramuscular, transdermal, or oral) can be considered for men with low or low-normal testosterone levels and concomitant problems with their sexual desire, erectile function and dissatisfaction derived from intercourse and overall sexual life (see section 3.6 for a comprehensive discussion of testosterone replacement therapy).

5.6.2.6 Vacuum erection devises

Vacuum erection devices (VED) provide passive engorgement of the corpora cavernosa, together with a constrictor ring placed at the base of the penis to retain blood within the corpora. Published data report that efficacy, in terms of erections satisfactory for intercourse, is as high as 90%, regardless of the cause of ED and satisfaction rates range between 27% and 94% [515, 516]. Most men who discontinue use of VEDs do so within three months. Long-term use of VEDs decreases to 50-64% after two years [517]. The most common adverse events include pain, inability to ejaculate, petechiae, bruising, and numbness [516]. Serious adverse events (skin necrosis) can be avoided if patients remove the constriction ring within 30 minutes. Vacuum erection devices are contraindicated in patients with bleeding disorders or on anticoagulant therapy [518, 519]. Vacuum erection devices may be the treatment of choice in well-informed older patients with infrequent sexual intercourse and comorbidities requiring non-invasive, drug-free management of ED [515, 516, 520].

5.6.2.7 Intracavernous injections therapy

Intracavernous administration of vasoactive drugs was the first medical treatment introduced for ED [477, 521]. According to invasiveness, tolerability, effectiveness and patients' expectations (Figure 6), patients may be offered intracavernous injections. The success rate is high (85%) [495, 522].

5.6.2.7.1 Alprostadil

Alprostadil (Caverject™, Edex/Viridal™) was the first and only drug approved for intracavernous treatment of ED [477, 523]. Intracavernous alprostadil is most efficacious as a monotherapy at a dose of 5-40 µg (of note 40 µg dose may be offered off label in some European countries). The erection appears after five to fifteen minutes and lasts according to the dose injected, but with significant heterogeneity among patients. An office-training

program is required for the patient to learn the injection technique. In men with limited manual dexterity, the technique may be taught to their partners. The use of an automatic pen that avoids a view of the needle may be useful to resolve fear of penile puncture and simplifies the technique.

Efficacy rates for intracavernous alprostadil of > 70% have been found in the general ED population, as well as in patient subgroups (e.g., diabetes or CVD), with reported satisfaction rates of 87-93.5% in patients and 86-90.3% in partners after the injections, respectively [477, 521]. Complications of intracavernous alprostadil include penile pain (50% of patients reported pain only after 11% of total injections), excessively-prolonged undesired erections (5%), priapism (1%), and fibrosis (2%) [477, 521, 524]. Pain is usually self-limited after prolonged use. It can be alleviated with the addition of sodium bicarbonate or local anaesthesia [477, 521, 525]. Cavernosal fibrosis (from a small haematoma) usually clears within a few months after temporary discontinuation of the injection program. However, tunical fibrosis suggests early onset of Peyronie's disease and may indicate stopping intracavernous injections indefinitely. Systemic side-effects are uncommon. The most common is mild hypotension, especially when using higher doses. Contraindications include men with a history of hypersensitivity to alprostadil, men at risk of priapism, and men with bleeding disorders. Despite these favourable data, drop-out rates of 41-68% have been described for intracavernous pharmacotherapy [477, 521, 526, 527], with most drop-outs occurring within the first two to three months. In a comparative study, alprostadil monotherapy had the lowest discontinuation rate (27.5%) compared to overall drug combinations (37.6%), with an attrition rate after the first few months of therapy of 10% per year [528]. Reasons for discontinuation included desire for a permanent modality of therapy (29%), lack of a suitable partner (26%), poor response (23%) (especially among early drop-out patients), fear of needles (23%), fear of complications (22%), and lack of spontaneity (21%). Careful counselling of patients during the office-training phase as well as close follow-up is important in addressing patient withdrawal from an intracavernous injection program [529-531].

5.6.2.8 Combination therapy

Table 16 details the available intracavernous injection therapies (compounds and characteristics). Combination therapy enables a patient to take advantage of the different modes of action of the drugs being used, as well as alleviating side-effects by using lower doses of each drug.

- Papaverine (20-80 mg) was the first oral drug used for intracavernous injections. It is most commonly used in combination therapy due to its high incidence of side-effects as monotherapy. Papaverine is currently not licensed for the treatment of ED.
- Phentolamine has been used in combination therapy to increase efficacy. As monotherapy, it produces a poor erectile response.
- Sparse data in the literature support the use of other drugs, such as vasoactive intestinal peptide (VIP), NO donors (linsidomine), forskolin, potassium channel openers, moxisylyte or calcitonin gene-related peptide, usually combined with the main drugs [532, 533]. Most combinations are not standardised and some drugs have limited availability worldwide.
- Bimix, Trimix: Papaverine (7.5-45 mg) plus phentolamine (0.25-1.5 mg) (also known as bimix), and papaverine (8-16 mg) plus phentolamine (0.2-0.4 mg) plus alprostadil (10-20 µg) (also known as trimix), have been widely used with improved efficacy rates, although they have never been licensed for ED [534, 535]. Trimix has the highest efficacy rates, reaching 92%; this combination has similar side-effects as alprostadil monotherapy, but a lower incidence of penile pain due to lower doses of alprostadil. However, fibrosis is more common (5-10%) when papaverine is used (depending on total dose).
- Invicorp: Vasoactive intestinal peptide (25 µg) plus phentolamine mesylate (1-2 mg Invicorp™), currently licensed in Scandinavia, is a combination of two active components with complementary modes of action. Clinical studies showed that the combination is an effective treatment for intracavernous injections in > 80% of men with ED, including those who have failed to respond to other therapies and, unlike existing intracavernous therapies, is associated with a very low incidence of penile pain and a virtually negligible risk of priapism [536].

Despite high efficacy rates, 5-10% of patients do not respond to combination intracavernous injections. The combination of sildenafil with intracavernous injection of the triple combination regimen may salvage as many as 31% of patients who do not respond to the triple combination alone [537]. However, combination therapy is associated with an increased incidence of adverse effects in 33% of patients, including dizziness in 20% of patients. This strategy can be considered in carefully selected patients before proceeding to a penile implant.

Table 16: Intracavernous injection therapy - compounds and characteristics

Name	Substance	Dosage	Efficacy	Adverse Events	Comment
Caverject™ or Edex/Viridal™	Alprostadil	5-40 µg/mL	~ 70%	Penile pain, priapism, fibrosis	Easily available
Papaverine	Papaverine	20 - 80 mg	< 55%	Elevation of liver enzymes, priapism, fibrosis	Abandoned as monotherapy
Phentolamine	Phentolamine	0.5 mg/mL	Very poor efficacy as monotherapy	Systemic hypotension, reflextachycardia, nasal congestion, and gastrointestinal upset	Abandoned as monotherapy
Bimix	Papaverine + Phentolamine	30 mg /mL + 0.5 mg/mL	~ 90%	Similar as Alprostadil (less pain)	Not licensed for the treatment of ED
Trimix	Papaverine + Phentolamine + Alprostadil	30 mg/mL + 1 mg /mL + 10 µg/ mL	~ 92%	Similar as Alprostadil (less pain)	Not licensed for the treatment of ED
Invicorp™	Vasoactive intestinal peptide (VIP) + Phentolamine	25 µg + 1-2mg	~ 80%	Similar as Alprostadil without pain	Easily available

There are currently several potential novel treatment modalities for ED, from innovative vasoactive agents and trophic factors to stem cell therapy and gene therapy. Most of these therapeutic approaches require further investigation in large-scale, blinded, placebo-controlled randomised studies in order to achieve an adequate evidence base and clinically-reliable grade of recommendation [538-543].

5.6.2.8.1 Erectile dysfunction after radical prostatectomy

Use of pro-erectile drugs following RP is important in achieving post-operative erectile function and to allow patients to resume sexual activity. There is also some evidence in animal studies that this may avoid cavernous fibrosis and maintain penile length. Overall, a number of trials have shown improvements in erectile function after RP in patients receiving drug compounds (any therapeutic or prophylactic) for ED. Early compared with delayed erectile function treatment seems to impact on the natural recovery time for potency [544], although there is a lack of data to support any specific regimen, which is either optimal for penile rehabilitation or may result in the achievement of spontaneous, non-pharmacological assisted erections [343, 545, 546]. In prospective studies, there is no evidence that penile rehabilitation itself increases the chances of spontaneous recovery of erectile function in men following NSRP [546]. Currently available therapeutic armamentarium follows the treatment algorithm for ED which is shown in Figure 4.

Historically, also the management of post-RP ED has been revolutionised by the advent of PDE5Is, with their demonstrated efficacy, ease of use, good tolerability, excellent safety, and positive impact on QoL. In this context, it must be emphasised that post-RP, ED patients are poor responders to PDE5Is. Since their launch on the market, PDE5Is have been considered as the first-line therapy in patients who have undergone NS surgery, regardless of the surgical technique used [343, 352, 353]. A number of clinical parameters have been identified as potential predictors of PDE5Is in men undergoing RP. As detailed, patient age, baseline erectile function, and quality of NS technique are key factors in preserving post-RP erectile function [352, 353, 361, 547].

Analysing results in further detail, the response rate to sildenafil treatment for ED after RP in different trials has ranged from 35% to 75% among those who underwent NSRP and from 0% to 15% among those who underwent non-NSRP [352, 548]. Early use of high-dose sildenafil after RP is associated with preservation of smooth muscle within the corpora cavernosa [549]. A single study demonstrated that daily sildenafil also results in a greater return of spontaneous normal erectile function after RP compared to placebo following bilateral NSRP in patients who were fully potent before surgery [550]. Conversely, a recent prospective, randomised, placebo-controlled study, which assessed the effects of nightly sildenafil citrate therapy during penile rehabilitation using nocturnal penile rigidity score in addition to the IIEF-erectile function showed no

therapeutic benefit for nightly sildenafil when compared to on-demand dosing in recovery of erectile function post-prostatectomy [551].

A large multicentre trial in Europe and the USA investigated the effects of tadalafil in patients with ED following bilateral NSRP. Erectile function was improved in 71% of patients treated with 20 mg tadalafil versus 24% of those treated with placebo, while the rate of successful intercourse attempts was 52% with 20 mg tadalafil versus 26% with placebo [552]. Moreover, a randomised, double-blind, double-placebo trial in men < 68 years of age and with normal pre-operative erectile function who underwent NSRP at 50 centres from nine European countries and Canada, compared tadalafil once daily with placebo [546]. Tadalafil was most effective for drug-assisted erectile function in men with ED following NSRP and data suggested a potential role for tadalafil once daily (provided early after surgery) in contributing to the recovery of post-operative erectile function and maintaining penile length [546]. Conversely, unassisted or spontantaeous recovery of erectile function was not improved after cessation of active therapy for nine months [546]. However, tadalafil once daily improved QoL post-operatively, both at double-blind treatment and open label treatment period [553].

Similarly, vardenafil has been tested in patients with ED following NSRP in a randomised, multicentre, prospective, placebo-controlled study [554]. Following bilateral NSRP, erectile function improved by 71% and 60% with 10 and 20 mg vardenafil, respectively. An extended analysis of the same cohort of patients showed the benefit of vardenafil compared to placebo in terms of intercourse satisfaction, hardness of erection, orgasmic function, and overall satisfaction with sexual experience [555]. A randomised, double-blind, double-dummy, multicentre, parallel-group study in 87 centres across Europe, Canada, South Africa and the USA, compared on-demand and nightly dosing of vardenafil in men with ED following bilateral NSRP [545]. In patients whose pre-operative erectile function domain score was > 26, vardenafil was efficacious when used on demand [545].

A double-blind, placebo-controlled, parallel-group study in 298 patients with ED after bilateral NSRP randomised to 100 or 200 mg avanafil or placebo (taken 30 minutes before sexual activity) for twelve weeks showed significantly greater increases in SEP question 2 and SEP3 as well as in mean change of IIEF erectile function domain score with 100 and 200 mg avanafil versus placebo ($p < 0.01$) [391].

A recent Cochrane database systematic review analysed data from eight RCTs [556]. It showed that scheduled PDE5I may have little or no effect on short-term (up to twelve months) self-reported potency when compared to placebo or no treatment. In this study, daily PDE5I made little to no difference in short-term and long-term erectile function (short term: RR 1.00, 95% CI 0.65 to 1.55; long term: RR 0.74, 95% CI 0.48 to 1.14; both very low quality evidence). The authors conclude that penile rehabilitation strategies using PDE5I following RP do not increase self-reported potency and erectile function compared to on-demand use. Therefore, daily PDE5Is appeared to result in little to no difference in both short-term and long-term (greater than twelve months) self-reported potency when compared to scheduled use. Finally, at short-term follow-up, daily PDE5I may result in little or no effect on self-reported potency when compared to scheduled intra-urethral application of PGE1.

Historically, the treatment options for post-RP ED have included intracavernous injections [557], urethral micro-suppository [352, 558], vacuum device therapy [343, 352, 559, 560], and penile implants [352, 561, 562]. Intracavernous injections and penile implants had been suggested as second- and third-line treatments, respectively, when oral PDE5Is are not adequately effective or not usable for post-operative patients [342, 343, 563]. A recent meta-analysis showed that the early use of vacuum device therapy appears to have excellent therapeutic effect on post-RP patients and no serious side-effects, therefore it should be considered as a therapeutic alternative to discuss with the patient [564].

5.6.2.9 Vascular surgery

5.6.2.9.1 Surgery for post-traumatic arteriogenic ED

In young patients with pelvic or perineal trauma, surgical penile revascularisation has a 60-70% long-term success rate [519, 565]. The stenosis must be confirmed by penile pharmaco-arteriography. Corporeal veno-occlusive dysfunction is a contraindication to revascularisation and must be excluded by dynamic infusion cavernosometry or cavernosography.

5.6.2.9.2 Venous ligation surgery

Venous ligation surgery for veno-occlusive dysfunction is no longer recommended because of poor long-term results [565].

5.6.2.9.3 Penile prostheses

The surgical implantation of a penile prosthesis may be considered in patients who (i) are not suitable for different pharmacotherapies or prefer a definitive therapy; and, (ii) do not respond to pharmacological therapies (Figure 6) [566]. The two currently available classes of penile implants include inflatable (2- and 3-piece) and semi-rigid devices (malleable, mechanical, soft flexible) [352, 561, 567-569]. Patients may prefer the 3-piece inflatable devices due to the more "natural" erections obtained, although there are no prospective RCTs comparing satisfaction rates with both types of implants. The two-piece inflatable prosthesis can be a viable option among patients who are deemed at high-risk of complications with reservoir placements (e.g., previous abdominal surgery). Semi-rigid prostheses result in a firm penis, which may be manually placed in an erect or flaccid state and offer the advantage of a simple implant technique, as well as easy use for the patient [352, 561, 567, 568]. Conversely, they can have the disadvantage of unnatural persistent erection and reduced concealability [568, 570]. They may also be an option in men with limited manual dexterity.

There are two main surgical approaches for penile prosthesis implantation: peno-scrotal and infrapubic [567, 568, 570, 571]. The peno-scrotal approach has been suggested to provide an excellent exposure; afford proximal crural exposure; avoid dorsal nerve injury; and permit direct visualisation of pump placement. However, with this approach, the reservoir is either placed blindly into the retropubic space, which can result in visceral injury in patients with a history of major pelvic surgery (mainly radical cystectomy) or a separate incision in the abdomen is placed under direct vision. A recent systematic review comparing the satisfaction and complication rates of the different surgical approaches showed that there is no specific advantage between the two, but rather it is recommended that the surgeon has knowledge of both techniques and is capable of tailoring the incision strategy for complex cases [572]. Revision surgery is associated with poorer outcomes and may be more challenging. Regardless of the indication, prosthesis implantation has one of the highest satisfaction rates (92-100% in patients and 91-95% in partners) among the treatment options for ED with appropriate counselling [352, 561, 567, 573-581]. In patients with favourable oncologic prognosis after RP for PCa, combination surgery for treatment of ED, with the implant of a penile prosthesis, and stress urinary incontinence (male sling or artificial urinary sphincter) is effective and durable and has an established and definitive role to address both problems [352, 561, 582-584]. Structured psychosexual counselling may improve sexuality and sexual well-being in both patients and their partners after penile implant surgery [585].

5.6.2.9.4 Penile prostheses implantation: complications

The two main complications of penile prosthesis implantation are mechanical failure and infection. Several technical modifications of the most commonly used 3-piece prosthesis (e.g., AMS 700CX/CXR™ and Titan Zero degree™) resulted in mechanical failure rates of < 5% after five years of follow-up [561, 586, 587]. Careful surgical techniques with appropriate antibiotic prophylaxis against Gram-positive and Gram-negative bacteria reduced infection rates to 2-3% with primary implantation in low-risk patients and in high volume centres, although the definition of a high volume centre still needs clarity [588-591]. The infection rate may be further reduced to 1-2% by implanting an antibiotic-impregnated prosthesis (AMS Inhibizone™) or hydrophilic-coated prosthesis (Coloplast Titan™) [561, 588, 592-595]. Methods that decrease infections include using coated prostheses and strictly adhering to surgical techniques that avoid prolonged wound exposure and skin contact minimisation (i.e. no-touch technique). Techniques that might prevent penile prostheses infection but lack definitive evidence include the use of prolonged post-operative antibiotics (> 24 hours), shaving with clippers, and prepping with chlorhexidine-alcohol [596]. Furthermore, identification and pre-treatment of patients who are colonised with nasal *Staphylococcus aureus* with mupirocin and chlorhexidine prior to surgery has been shown to reduce the incidence of surgical site infection after surgery from 4.4% to 0.9% in a placebo-controlled randomised trial [597]. On the whole, growing evidence suggests that the risk of penile prosthesis infection has reduced over the last few decades with device improvement and surgical expertise [598].

Higher-risk populations include patients undergoing revision surgery, those with impaired host defences (immunosuppression, diabetes mellitus, spinal cord injury) or those with penile corporal fibrosis [561, 567, 589, 599-601]. A recent large database-study showed that diabetes mellitus is a risk factor for penile prostheses infection, highlighting the need for an optimal patient selection other than raising the question of whether lowering this risk by optimising glycaemic control before surgery [602]. Unfortunately, there are no RCTs determining the ideal and/or correct threshold of glycated haemoglobin that is acceptable prior to implant surgery in diabetic patients [603].

Infection requires removal of the prosthesis and antibiotic administration. Alternatively, removal of the infected device with immediate replacement with a new prosthesis has been described using a wash-out protocol with successful salvages achieved in > 80% of cases [589, 600, 604, 605]. A final recommendation on how to proceed after removal in this setting cannot be given. The majority of revisions are secondary to mechanical

failure and combined erosion or infection [594, 596]. Ninety-three percent of cases are successfully revised, providing functioning penile prosthesis [588, 589, 604, 606, 607].

Besides infection and mechanical failure, impending erosion involving the distal lateral corpora, urethra, glans or other structures can occur in 1-6% of cases after surgery [608]. Similarly glans ischaemia and necrosis have been reported in about 1.5% of patients [609]. Risk factors for these serious complications are higher in those patients with significant vascular impairment, such as patients with diabetes, or who have undergone concomitant lengthening procedures.

5.6.2.9.4.1 Conclusions penile prostheses implantation

Penile implants are an effective solution for patients who do not respond to more conservative therapies. There is sufficient evidence to recommend this approach in patients not responding to less-invasive treatments due to its high efficacy, safety and satisfaction rates [610]. There are also currently no head to head studies comparing the different manufacturers' implants, demonstrating superiority of one implant type over another.

5.6.3 *Recommendations for the treatment of ED*

Recommendations	Strength rating
Assess all patients for inadequate/incorrect information about the mechanism of action and the ways in which drugs should be taken, as they are the main causes of a lack of response to PDE5Is.	Weak
Use Cognitive Behaviour Therapy as psychological approach (include the partner) combined with medical treatment to maximise treatment outcomes.	Strong
Discuss with patients undergoing radical prostatectomy (any technique) about the risk of sexual changes other than ED, including libido reduction, changes in orgasm, anejaculation, Peyronie's like disease and penile size changes.	Strong
Initiate lifestyle changes and risk factor modification prior to or at the same time as initiating erectile dysfunction (ED) treatments.	Strong
Treat a curable cause of ED first, when found.	Weak
Use phosphodiesterase type 5 inhibitors (PDE5Is) as first-line therapeutic options.	Strong
Use topical/intraurethral alprostadil as an alternative first-line therapy in well-informed patients who do not wish or are not suitable for oral vasoactive therapy.	Weak
Use topical/intraurethral alprostadil as an alternative therapy to intracavernous injections in patients who prefer a less-invasive therapy.	Weak
Use low intensity shockwave treatment (LI-SWT) in patients with mild vasculogenic ED or as an alternative first-line therapy in well-informed patients who do not wish or are not suitable for oral vasoactive therapy or desire a curable option. Use LI-SWT in vasculogenic ED patients who are poor responders to PDE5Is.	Weak
Use vacuum erection devices as a first-line therapy in well-informed patients with infrequent sexual intercourse and comorbidities requiring non-invasive, drug-free management of ED.	Weak
Use intracavernous injections as an alternative first-line therapy in well-informed patients or as second-line therapy.	Strong
Use implantation of a penile prosthesis if other treatments fail or based upon patient preference.	Strong
Data is inadequate to support the use of any specific regimen for penile rehabilitation after radical prostatectomy.	Strong
Pro-erectile treatments should start at the earliest opportunity after radical prostatectomy/ pelvic surgery and other curative treatments for prostate cancer.	Weak

5.6.4 *Follow-up*

Follow-up is important in order to assess efficacy and safety of the treatment provided. It is also essential to assess patient satisfaction since successful treatment for ED goes beyond efficacy and safety. Physicians must be aware that there is no single treatment that fits all patients or all situations as described in detail in the previous section.

6. DISORDERS OF EJACULATION

6.1 Introduction

Ejaculation is a complex physiological process which is composed of emission and expulsion and is mediated by interwoven neurological and hormonal pathways [611]. Any interference with those pathways may cause a wide range of ejaculatory disorders (Table 18).

Table 18: Spectrum of ejaculation disorders

Premature ejaculation
Retarded or delayed ejaculation
Anejaculation
Painful ejaculation
Retrograde ejaculation
Anorgasmia
Haemospermia

6.2 Premature ejaculation

*6.2.1 **Epidemiology***

Historically, the main problem in assessing the prevalence of premature ejaculation (PE) has been the lack of a universally recognised definition at the time the surveys were conducted [172]. In this context, the highest prevalence rate of 31% (men aged 18-59 years) was found by the USA National Health and Social Life Survey (NHSLS) study [177]. Prevalence rates were 30% (18-29 years), 32% (30-39 years), 28% (40-49 years) and 55% (50-59 years). It is, however, unlikely that PE prevalence was as high as 20-30% based on the relatively low number of men who presented for treatment of PE. These high prevalence rates may be a result of the dichotomous scale (yes/no) in a single question, asking if ejaculation occurred too early. The Internet-based survey PEPA [the PE Prevalence and Attitudes] revealed a 22.7% prevalence of PE (24.0% in the United States, 20.3% in Germany, and 20% in Italy), which did not vary significantly with age among men over 24 years of age [178]. According to the four PE subtypes proposed by Waldinger *et al.* [181], the prevalence rates were 2.3% (lifelong PE), 3.9% (acquired PE), 8.5% (variable PE) and, 5.1% (premature-like ED or subjective PE) [179]. A prevalence of approximately 5% of acquired PE and lifelong PE in the general population is consistent with epidemiological data indicating that around 5% of the population have an ejaculation latency time of less than two minutes [185].

*6.2.2 **Pathophysiology and risk factors***

The aetiology of PE is unknown, with little data to support suggested biological and psychological hypotheses, including anxiety [612-616], penile hypersensitivity [617-623] and 5-hydroxytryptamine (HT) receptor dysfunction [624-629]. The classification of PE into four subtypes [181] has contributed to a better delineation of lifelong, acquired, variable and subjective PE [630-632]. It has been hypothesised that the pathophysiology of lifelong PE is mediated by a very complex interplay of central and peripheral serotonergic, dopaminergic, oxytocinergic, endocrinological, genetic and epigenetic factors [633]. On the other hand, acquired PE may occur due to either psychological problems - such as sexual performance anxiety, psychological or relationship problems - and/or comorbid medical conditions, including ED, prostatitis and hyperthyroidism [634-636].

A significant proportion of men with ED also experience PE [188, 334]. High levels of performance anxiety related to ED may worsen PE, with a risk of misdiagnosing PE instead of the underlying ED. According to the NHSLS, the prevalence of PE is not affected by age [177], unlike ED, which increases with age. Conversely, other data depicted an increased prevalence with ageing [637]; for instance, Verze *et al.* reported that PE prevalence based on the Premature Ejaculation Diagnostic Tool (PEDT) score (≥ 11) [638] proportionally increased with age [639]. Premature ejaculation is not affected by marital or income status [177, 639]. However, PE is more common in Black men, Hispanic men, and men from regions where the Islamic background is particularly common [176, 640] and may be higher in men with a lower educational level [177, 188]. Other risk factors may include a genetic predisposition [629, 641-644], poor overall health status and obesity [177], prostate inflammation [323, 645-648], low prolactin levels [649], higher testosterone levels [650], vitamin D and B12 deficiency [651, 652], diabetes [653, 654], metabolic syndrome [654, 655], lack of physical activity [656], emotional problems and stress [177, 657, 658], depressive symptoms [658], and traumatic sexual experiences [177, 188]. In the only published study on risk modification/prevention strategies [659], successful eradication of causative organisms in patients with chronic prostatitis and PE produced marked improvements in intravaginal ejaculatory latency time (IELT) and ejaculatory control compared to untreated patients.

*6.2.3 **Impact of premature ejaculation on quality of life***

Men with PE are more likely to report low satisfaction with their sexual relationship, low satisfaction with sexual intercourse, difficulty relaxing during intercourse, and less frequent intercourse [257, 660, 661]. However, the negative impact of PE extends beyond sexual dysfunction. Premature ejaculation can have a detrimental effect on self-confidence and the relationship with the partner, and may sometimes cause mental distress, anxiety, embarrassment and depression [257, 662, 663]. Moreover, PE may impact on the partner's sexual functioning

and their satisfaction with the sexual relationship decreases with increasing severity of the patients' condition [664-666]. Despite the possible serious psychological and QoL consequences of PE, few men seek treatment. In the Global Study of Sexual Attitudes and Behaviors (GSSAB) survey, 78% of men who self-reported a sexual dysfunction sought no professional help or advice for their sexual problems [188], with men more likely to seek treatment for ED than for PE [188]. In the PEPA survey, only 9% of men with self-reported PE consulted a doctor [178]. The main reasons for not discussing PE with their physician are embarrassment and a belief that there is no treatment. Physicians are often uncomfortable discussing sexuality with their patients usually because of embarrassment and a lack of training or expertise in treating PE [667, 668]. Physicians need to encourage their patients to talk about PE.

*6.2.4 **Classification***

There is still little consensus about the definition and classification of PE [669]. It is now universally accepted that "premature ejaculation" is a broad term that includes a number of concepts belonging to the common category of PE. The most recent definition comes from the International Classification of Diseases 11th Revision, where PE was renamed as Early Ejaculation [670]: *"Male early ejaculation is characterized by ejaculation that occurs prior to or within a very short duration of the initiation of vaginal penetration or other relevant sexual stimulation, with no or little perceived control over ejaculation. The pattern of early ejaculation has occurred episodically or persistently over a period of at least several months and is associated with clinically significant distress."*

This definition includes five categories: male early ejaculation, lifelong generalised and situational, acquired generalised and situational, unspecified.

In the Diagnostic and Statistical Manual of Mental Disorders V (DSM-V), PE is defined as a sexual disorder with:

- consistent ejaculation within one minute or less of vaginal penetration;
- over a period of at least six months;
- experienced 75%-100% of the time;
- the condition results in clinically significant distress, sexual frustration, dissatisfaction, or tension between partners;
- this condition is not better accounted for by another non-sexual mental disorder, medication or illicit substance use, or medical condition [671].

The EAU Guidelines have adopted the definition of PE which has been developed by the International Society for Sexual Medicine (ISSM) as the first evidence-based definition [672]. According to this definition, PE (lifelong and acquired) is a male sexual dysfunction characterised by the following:

- Ejaculation that always or nearly always occurs prior to or within about one minute of vaginal penetration (lifelong PE) or a clinically significant and bothersome reduction in latency time, often to about three minutes or less (acquired PE).
- The inability to delay ejaculation on all or nearly all vaginal penetrations.
- Negative personal consequences, such as distress, bother, frustration, and/or the avoidance of sexual intimacy.

Two more PE syndromes have been proposed [631]:

- 'Variable PE' is characterised by inconsistent and irregular early ejaculations, representing a normal variation in sexual performance.
- 'Subjective PE' is characterised by subjective perception of consistent or inconsistent rapid ejaculation during intercourse, while ejaculation latency time is in the normal range or can even last longer. It should not be regarded as a symptom or manifestation of true medical pathology.

The addition of these new types may help in overcoming the limitations of each individual definition and it may support a more flexible view of PE for patient stratification, diagnosis and treatment [673].

6.2.5 Diagnostic evaluation

Diagnosis of PE is based on the patient's medical and sexual history [185, 674, 675]. History should classify PE as lifelong or acquired and determine whether PE is situational (under specific circumstances or with a specific partner) or consistent. Special attention should be given to the duration time of ejaculation, degree of sexual stimulus, impact on sexual activity and QoL, and drug use or abuse. It is also important to distinguish PE from ED. Many patients with ED develop secondary PE caused by the anxiety associated with difficulty in attaining and maintaining an erection [334, 676]. Furthermore, some patients are not aware that loss of erection after ejaculation is normal and may erroneously complain of ED, while the actual problem is PE [677]. There are several overlapping definitions of PE, with four shared factors (Table 19), resulting in a multi-dimensional diagnosis [678].

Table 19: Common factors in different definitions of PE

Time to ejaculation assessed by IELT
Perceived control
Distress, bother, frustration, interpersonal difficulty related to the ejaculatory dysfunction

6.2.5.1 Intravaginal ejaculatory latency time

Although it has been suggested as an objective diagnostic criterion and treatment outcome measure [679, 680], the use of IELT alone is not sufficient to define PE, as there is significant overlap between men with and without PE [681, 682]. Moreover, some men may experience PE in their non-coital sexual activities (e.g. during masturbation, oral sex or anal intercourse) thus measuring IELT will not be suitable for their assessment. IELT has a significant direct effect on perceived control over ejaculation, but not a significant direct effect on ejaculation-related personal distress or satisfaction with sexual intercourse [683]. In addition, perceived control over ejaculation has a significant direct effect on both ejaculation-related personal distress and satisfaction with sexual intercourse (each showing direct effects on interpersonal difficulty related to ejaculation) [684]. In everyday clinical practice, self-estimated IELT is sufficient [173]. Self-estimated and stopwatch-measured IELT are interchangeable and correctly assign PE status with 80% sensitivity and 80% specificity [685]. Specificity can be improved further to 96% by combining IELT with a single-item patient-reported outcome (PRO) scale on control over ejaculation and satisfaction with sexual intercourse (scale ranging from 0 = very poor to 4 = very good) and on personal distress and interpersonal difficulty (0 = not at all, to 4 = extremely). However, self-estimated IELT may be over-estimated by approximately one minute and therefore it must be carefully substituted with stopwatch-measured IELT while identifying men with the complaint of lifelong PE in a clinical setting [686].

On the other hand, measurement of IELT with a calibrated stopwatch is mandatory in clinical trials. For any drug treatment study of PE, Waldinger *et al.* suggested using geometric mean IELT instead of using arithmetic mean IELT as the distributed IELT data are skewed. Otherwise, any treatment-related ejaculation delay may be overestimated if the arithmetic mean IELT is used instead of the geometric mean IELT [687].

6.2.5.2 Premature ejaculation assessment questionnaires

The need to assess PE objectively has led to the development of several questionnaires based on the use of PROs. Only two questionnaires can discriminate between patients who have PE and those who do not:

- Premature Ejaculation Diagnostic Tool (PEDT): A five-item questionnaire based on focus groups and interviews from the USA, Germany, and Spain assesses control, frequency, minimal stimulation, distress and interpersonal difficulty [688]. A total score > 11 suggests a diagnosis of PE, a score of 9 or 10 suggests a probable diagnosis of PE while a score of < 8 indicates a low likelihood of PE.

- Arabic Index of Premature Ejaculation (AIPE): A seven-item questionnaire developed in Saudi Arabia assesses sexual desire, hard erections for sufficient intercourse, time to ejaculation, control, satisfaction of the patient and partner, anxiety or depression [689]. A cut-off score of 30 (range of scores 7-35) discriminated PE diagnosis best. Severity of PE was classified as severe (score: 7-13), moderate (score: 14-19), mild-to-moderate (score: 20-25) and mild (score: 26-30).

Although it is widely used, some studies reported a low correlation between a diagnosis provided by PEDT and a self-reported diagnosis. Only 40% of men with PEDT-diagnosed PE and 19% of men with probable PE self-reported the condition [274]. On the contrary, a recent study has shown that the PEDT was highly valid in screening the presence of evidence-based-defined lifelong PE and acquired PE [62]. Questionnaires are a significant step in simplifying the methodology of PE drug studies, although further cross-cultural validation is needed [690].

Other questionnaires used to characterise PE and determine treatment effects include the Premature Ejaculation Profile (PEP) [682], Index of Premature Ejaculation (IPE) [691] and Male Sexual Health Questionnaire Ejaculatory Dysfunction (MSHQ-EjD) [692]. Currently, their role is optional in everyday clinical practice.

6.2.5.3 Physical examination and investigations

Physical examination may be part of the initial assessment of men with PE. It may include a focused examination of the urological, endocrine and neurological systems to identify underlying medical conditions

associated with PE or other sexual dysfunctions, such as endocrinopathy, Peyronie's disease, urethritis or prostatitis. Laboratory or physiological testing should be directed by specific findings from history or physical examination and is not routinely recommended [674].

6.2.5.4 Recommendations for the diagnostic evaluation of PE

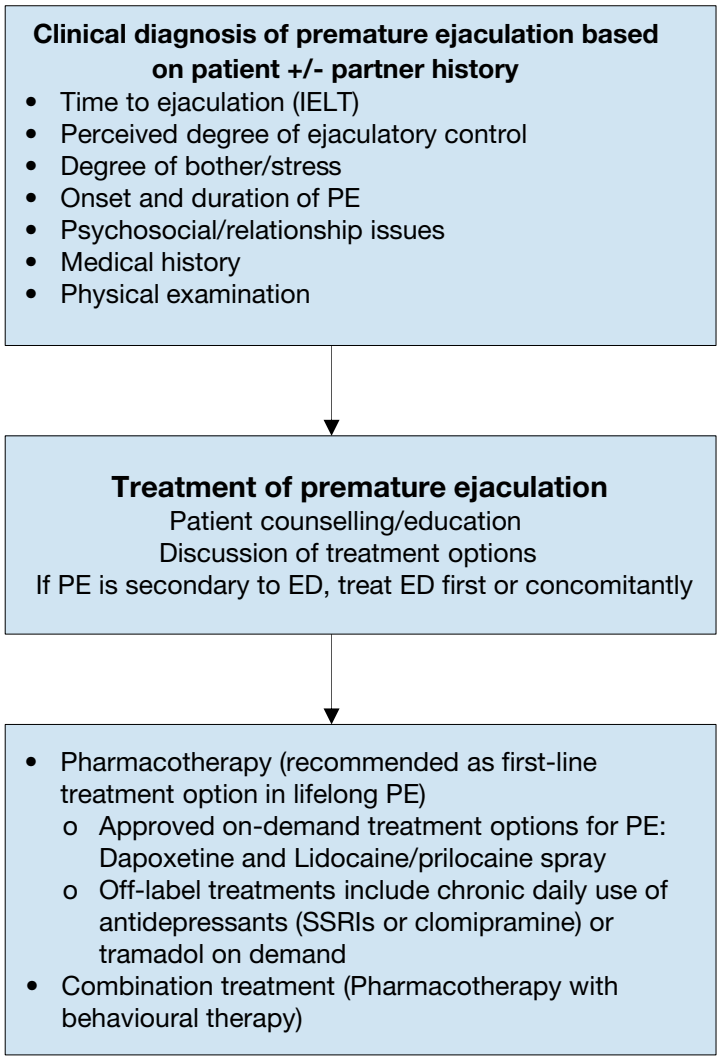
Recommendations	Strength rating
Perform the diagnosis and classification of premature ejaculation (PE) based on medical and sexual history, which should include assessment of intravaginal ejaculatory latency time (IELT) (self-estimated), perceived control, distress and interpersonal difficulty due to the ejaculatory dysfunction.	Strong
Use of stopwatch-measured IELT is not compulsory in clinical practice.	Weak
Use patient-reported outcomes in daily clinical practice.	Weak
Include physical examination in the initial assessment of PE to identify anatomical abnormalities that may be associated with PE or other sexual dysfunctions, particularly erectile dysfunction (ED).	Strong
Do not perform routine laboratory or neuro-physiological tests. They should only be directed by specific findings from history or physical examination.	Strong

*6.2.6 **Disease management***

Before commencing any treatment, it is essential to define the subtype of PE and discuss patient's expectations thoroughly. Pharmacotherapy must be considered as the first-line treatment for patients with lifelong PE, whereas treating the underlying cause (e.g., ED, prostatitis, LUTS, anxiety, hyperthyroidism) must be the initial goal for patients with acquired PE [185]. Various behavioural techniques may be beneficial in treating variable and subjective PE [693]. Psychotherapy can also be considered for PE patients who are uncomfortable with pharmacological therapy or in combination with pharmacological therapy [694, 695]. However, there is weak and inconsistent evidence regarding the effectiveness of these psychosexual interventions and their long-term outcomes in PE are unknown [696].

In lifelong PE, behavioural techniques are not recommended alone, and pharmacotherapy must be considered as the basis of treatment [185]. Dapoxetine (30 and 60 mg) is the first on-demand oral pharmacological agent approved for lifelong and acquired PE in many countries, except for the USA [697]. Moreover, the metered-dose aerosol spray of lidocaine (150 mg/mL) and prilocaine (50 mg/mL) combination is the first topical formula to be officially approved for the on-demand treatment of lifelong PE by the EMA in the European Union [698]. All other medications used in PE are off-label indications [699]. Daily or on-demand use of selective serotonin re-uptake inhibitors (SSRIs) and clomipramine, and on-demand topical anaesthetic agents have consistently shown efficacy in PE [700-703]. Long-term outcomes of pharmacological treatments are unknown. An evidence-based analysis of all current treatment modalities was performed. Levels of evidence and grades of recommendation are provided, and a treatment algorithm is presented (Figure 7).

Figure 7: Management of premature ejaculation*



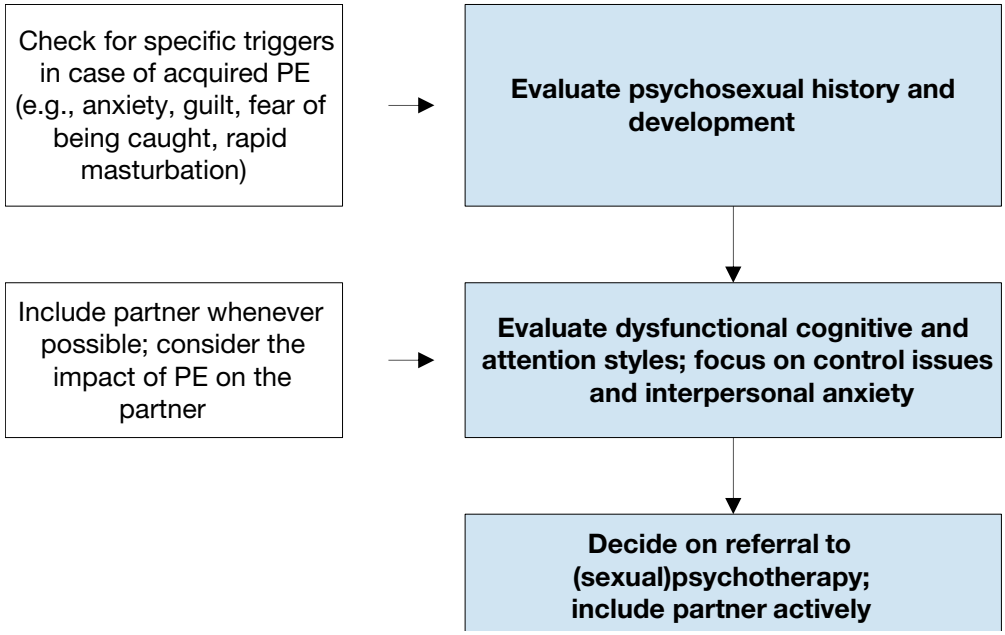
* Adapted from Lue *et al.* 2004 [704].
ED = erectile dysfunction; PE = premature ejaculation; IELT = intravaginal ejaculatory latency time; SSRI = selective serotonin receptor inhibitor.

6.2.6.1 Psychological aspects and intervention

Only a few studies have addressed the psychological factors underpinning PE. Men with PE were shown to present dysfunctional responsibility attribution patterns regarding their sexual experience. These men blamed themselves for their dysfunctional sexual response, even when the negative sexual outcome was unrelated to early ejaculation; additionally, they took less credit for any positive sexual experience they might have [705, 706]. In addition to this style of internalised blame, men with PE were found to focus on bodily sensations and partners' reactions during sex, in order to monitor potential signs of threat to their sexual performance. This monitoring process denotes a dysfunctional cognitive and attention style that contributes to the maintenance of PE [407]. Premature ejaculation has been further related to increased levels of anxiety, including social anxiety [407, 684]. Yet, it is not known whether anxiety is a precursor or a consequence of PE [613]. Furthermore, the negative impact of PE on the couple has been consistently mentioned. Female partners of men with PE present with an increased likelihood of sexual dysfunction [707]; the intimate sphere, as well as the overall relationship quality, was compromised by PE [696]. An important trigger for seeking help in PE is partner dissatisfaction and the negative impact of PE on the general QoL of the couple [708]. Accordingly, psychosexual interventions, whether these are behavioural, cognitive, or focused on the couple, are aimed at teaching techniques to control/delay ejaculation, gaining confidence in sexual performance, reducing anxiety, and promoting communication and problem solving within the couple [693]. Is worth noting, however, that psychosexual interventions alone regarding PE lack empirical support. Behavioural therapy may be most effective when used to 'add value' to medical interventions. A combination of dapoxetine and behavioural treatment was more effective than dapoxetine alone in patients with lifelong PE in a prospective, randomised

trial [694]. Validated assessment instruments need to be used as end-points. Longer follow-up periods are necessary to confirm these findings.

Figure 8: Key aspects for psychosexual evaluation



6.2.6.1.1 Recommendation for the assessment and treatment (psychosexual approach) of PE

Recommendations for assessment	**Strength rating**
Consider sexual history and psychosexual development.	Strong
Consider anxiety, interpersonal anxiety; focus on control issues.	Strong
Include partner if available; check for the impact of PE on the partner.	Strong
Recommendations for treatment (psychosexual approach)	
Use behavioural, cognitive and/or couple therapy approaches.	Weak

6.2.6.2 Pharmacotherapy

6.2.6.2.1 Dapoxetine

Dapoxetine hydrochloride is a short-acting SSRI, with a pharmacokinetic profile suitable for on-demand treatment for PE [699]. It has a rapid T_{max} (1.3 hours) and a short half-life (95% clearance rate after 24 hours) [709]. Dapoxetine has been investigated in 6,081 subjects to date [710]. It is approved for on-demand treatment of PE in European countries and elsewhere, but not in the USA. Both available doses of dapoxetine (30 mg and 60 mg) have shown 2.5- and 3.0-fold increases, respectively, in IELT overall, rising to 3.4- and 4.3-fold in patients with a baseline average IELT of < 0.5 minutes [697, 711, 712].

In RCTs, dapoxetine, 30 mg or 60 mg one to two hours before intercourse, was effective on IELT and increased ejaculatory control, decreased distress, and increased satisfaction [713]. Dapoxetine has shown a similar efficacy profile in men with lifelong and acquired PE [697, 714, 715]. Treatment-related side-effects were dose-dependent and included nausea, diarrhoea, headache, and dizziness. Treatment-emergent adverse events (TEAEs) were responsible for study discontinuation in 4% (30 mg) and 10% (60 mg) of subjects [173]. There was no indication of an increased risk of suicidal ideation or suicide attempts and little indication of withdrawal symptoms with abrupt dapoxetine cessation [716, 717]. Moreover, dapoxetine is found to be safer compared with formal anti-depressant compounds which are used for the treatment of PE [718].

A low rate (0.1%) of vasovagal syncope was reported in phase 3 studies [719]. According to the summary of product characteristics, orthostatic vital signs (blood pressure and heart rate) must be measured prior to starting dapoxetine and dose-titration must be considered [720]. The EMA assessment report for dapoxetine concluded that the potentially increased risk for syncope has been proven manageable with adequate risk minimisation measures [721]. No cases of syncope were observed in a post-marketing observational study, which had identified patients at risk for orthostatic reaction using the patient's medical history and orthostatic testing [722].

Many patients and physicians may prefer using dapoxetine in combination with a PDE5I in order to extend the time until ejaculation and minimise the risk of ED due to dapoxetine treatment. Phase 1 studies of dapoxetine have confirmed that it does not have any pharmacokinetic interactions with PDE5I (i.e. tadalafil 20 mg and sildenafil 100 mg) [723]. When dapoxetine is co-administered with PDE5Is, it is well tolerated, with a safety profile consistent with previous phase 3 studies of dapoxetine alone [724]. A recent RCT including PE patients without ED, demonstrated that combination of dapoxetine with sildenafil can significantly improve IELT values and PROs compared with dapoxetine alone or sildenafil alone, with tolerable adverse effects [725]. Efficacy and safety of dapoxetine/sildenafil combination tablets for the treatment of PE have also been reported [726].

6.2.6.2.2 Off-label use of antidepressants: SSRIs and clomipramine

Ejaculation is commanded by a spinal ejaculation generator [727, 728] under excitatory or inhibitory influences from the brain and the periphery [653]. 5-hydroxytryptamine (5-HT or serotonin) is involved in ejaculatory control, with its ejaculation-retarding effects likely to be attributable to activation of 5-HT_{1B} and 5-HT_{2C} receptors, both spinally and supraspinally. By contrast, stimulation of 5-HT_{1A} receptors precipitates ejaculation [729].

Selective serotonin re-uptake inhibitors are used to treat mood disorders but can delay ejaculation and therefore are widely used 'off-label' for PE since the 1990s [730]. For depression, SSRIs must be given for one to two weeks to be effective in PE [729]. Administration of chronic SSRIs causes prolonged increases in synaptic cleft serotonin, which desensitises the 5-HT_{1A} and 5-HT_{1B} receptors [731]. Commonly used SSRIs include continuous intake of citalopram, fluoxetine, fluvoxamine, paroxetine and sertraline, all of which have a similar efficacy, whereas paroxetine exerts the strongest ejaculation delay [679, 732, 733].

Clomipramine, the most serotoninergic tricyclic antidepressant, was first reported in 1977 as an effective PE treatment [734, 735]. In a recent RCT, on-demand use of clomipramine 15 mg, two to six hours before sexual intercourse was found to be associated with IELT fold change and significant improvements in PRO measures in the treatment group as compared to the placebo group (4.66 ± 5.64 vs. 2.80 ± 2.19, $p < 0.05$). [736, 737]. The most commonly reported TEAEs were nausea in 15.7% of men and dizziness in 4.9% [736, 737].

Several SRs and meta-analyses of drug treatment studies reported that, despite methodological problems in most studies, there still remained several, well-designed, double-blind, placebo-controlled trials supporting the therapeutic effect of daily SSRIs on PE [679, 700-703]. Based on these meta-analyses, SSRIs may increase the geometric mean IELT by 2.6-fold to 13.2-fold. Paroxetine was found to be superior to fluoxetine, clomipramine and sertraline. Sertraline was superior to fluoxetine, whereas the efficacy of clomipramine was not significantly different from fluoxetine and sertraline. Paroxetine was evaluated in doses of 20-40 mg, sertraline 25-200 mg, fluoxetine 10-60 mg and clomipramine 25-50 mg; there was no significant relationship between dose and response among the various drugs. There is limited evidence that citalopram may be less efficacious compared to other SSRIs, while fluvoxamine may not be effective [738, 739].

Ejaculation delay may start a few days after drug intake, but it is more evident after one to two weeks as receptor desensitisation requires time to occur. Although efficacy may be maintained for several years, tachyphylaxis (decreasing response to a drug following chronic administration) may occur after six to twelve months [734]. Common TEAEs of SSRIs include fatigue, drowsiness, yawning, nausea, vomiting, dry mouth, diarrhoea and perspiration; TEAEs are usually mild and gradually improve after two to three weeks of treatment [711, 734]. Decreased libido, anorgasmia, anejaculation and ED have also been reported.

Because of the risk of suicidal ideation or suicide attempts, caution is suggested in prescribing SSRIs to young adolescents with PE aged eighteen years or less, and to men with PE and a comorbid depressive disorder, particularly when associated with suicidal ideation. Patients should be advised to avoid sudden cessation or rapid dose reduction of daily-dosed SSRIs, which may be associated with a SSRI withdrawal syndrome [173]. Moreover, PE patients who are trying to conceive should avoid using these medications because of their detrimental effects on sperm cells [740-743].

6.2.6.2.3 Topical anaesthetic agents

The use of local anaesthetics to delay ejaculation is the oldest form of pharmacological therapy for PE [744].
Several trials [620, 745, 746] support the hypothesis that topical desensitising agents reduce the sensitivity of the glans penis thereby delaying ejaculatory latency, but without adversely affecting the sensation of ejaculation. Meta-analyses confirmed the efficacy and safety of these agents for the treatment of PE [747, 748].

6.2.6.2.3.1 Lidocaine-prilocaine cream

In a randomised, double-blind, placebo-controlled trial, lidocaine/prilocaine cream increased the IELT from one minute in the placebo group to 6.7 minutes in the treatment group [749]. In another randomised, double blind, placebo-controlled trial, lidocaine/prilocaine cream significantly increased the stopwatch-measured IELT from 1.49 to 8.45 minutes, while no difference was recorded in the placebo group (1.67 to 1.95 minutes) [750]. Although no significant TEAEs have been reported, topical anaesthetics are contraindicated in patients or partners with an allergy to any ingredient in the product. Moreover, these anaesthetic creams/gels may be transferred to the partner and result in vaginal numbness. Therefore, patients are advised to use a condom after applying the cream on their penises. Alternatively, the penis can be washed clean of any residual active compound prior to sexual intercourse. Since these chemicals may be associated with cytotoxic effects on fresh human sperm cells, couples who are wanting to achieve pregnancy should not use topical lidocaine/prilocain containing substances [751].

6.2.6.2.3.2 Lidocaine-prilocaine spray

The eutectic lidocaine/prilocaine spray is a metered-dose aerosol spray containing purely base forms of lidocaine (150 mg/mL) and prilocaine (50 mg/mL) which has been officially approved by the EMA for the treatment of males with lifelong PE [752]. Compared to topical creams, the metered-dose spray delivery system has been proved to deposit the drug in a dose-controlled, concentrated film covering the glans penis, maximising neural blockage and minimising the onset of numbness [753], without absorption through the penile shaft skin [754].

To date, one phase 2 proof-of-concept [754] and two phase 3 RCTs [755, 756] have demonstrated the efficacy of lidocaine/prilocaine spray in improving both IELT and the Index of Ejaculatory Control (IEC) of patients with primary PE, along with an improvement in scores assessing treatment satisfaction (IPE) [755, 756]. Based on these data, according to the patient information leaflet [757], the recommended dose of lidocaine/prilocaine spray is one dose (namely three sprays) to be applied on the glans penis at least five minutes before sexual intercourse [758]. Published data showed that lidocaine/prilocaine spray increases IELT over time up to 6.3-fold over three months, with a month by month improvement through the course of the treatment in long term studies [759]. A low incidence of local TEAEs in both patients and partners have been reported, including genital hypoaesthesia (4.5% and 1.% in males and females partners, respectively) and ED (4.4%), and vulvovaginal burning sensation (3.9%), but is unlikely to be associated with systemic TEAEs [757, 760].

6.2.6.2.4 Tramadol

Tramadol is a centrally-acting analgesic agent that combines opioid receptor activation and re-uptake inhibition of serotonin and noradrenaline. Tramadol is a mild-opioid receptor agonist, but it also displays antagonistic properties on transporters of noradrenaline and 5-HT [761]. This mechanism of action distinguishes tramadol from other opioids, including morphine. Tramadol is readily absorbed after oral administration and has an elimination half-life of five to seven hours.

A large, randomised, double-blind, placebo-controlled, multicentre twelve-week study was carried out to evaluate the efficacy and safety of two doses of tramadol (62 and 89 mg) by ODT in the treatment of PE [762]. A bioequivalence study had previously been performed demonstrating equivalence between tramadol ODT and tramadol HCl. In patients with a history of lifelong PE and an IELT < two minutes, increases in the median IELT of 0.6 minutes (1.6-fold), 1.2 minutes (2.4-fold) and 1.5 minutes (2.5-fold) were reported for placebo, 62 mg of tramadol ODT, and 89 mg of tramadol ODT, respectively. It should be noted that there was no dose-response effect with tramadol. Side-effects were reported at doses used for analgesic purposes (up to 400 mg daily) and include constipation, sedation and dry mouth. However, in May 2009, the US FDA released a warning letter about tramadol's potential to cause addiction and difficulty in breathing [763]. The tolerability during the twelve-week study period in men with PE was acceptable. Several other studies also reported that tramadol exhibits a significant dose-related efficacy and side-effects over placebo for the treatment of PE [764]. Moreover, the efficacy and safety of tramadol have been confirmed in SRs and meta-analyses [765-767].

6.2.6.2.5 Phosphodiesterase type 5 inhibitors

There is one well-designed, randomised, double-blind, placebo-controlled study comparing sildenafil to placebo in men with PE [768]. Although IELT was not significantly improved, sildenafil increased confidence, the perception of ejaculatory control and overall sexual satisfaction, reduced anxiety and decreased the refractory time to achieve a second erection after ejaculation. Another RCT demonstrated that once-daily use of 5 mg tadalafil for six weeks is effective in improving PROs and is well tolerated by patients with PE [769].

Several open-label studies showed that PDE5Is combined with an SSRI is superior to SSRI monotherapy:

- Sildenafil combined with paroxetine improved IELT significantly and satisfaction versus paroxetine alone [770];
- Sildenafil combined with sertraline improved IELT and satisfaction significantly versus sertraline alone [771];
- Sildenafil combined with paroxetine and psychological and behavioural counselling significantly improved IELT and satisfaction in patients in whom other treatments failed [772];
- Sildenafil combined with dapoxetine (30 mg.) improved IELT, satisfaction scores and PEDT vs. dapoxetine, paroxetine or sildenafil monotherapy [725];
- Tadalafil combined with paroxetine significantly improved IELT and satisfaction versus paroxetine and tadalafil alone [773];
- Finally, sildenafil combined with behavioural therapy significantly improved IELT and satisfaction versus behavioural therapy alone [774].

There are very limited data on the efficacy of other PDE5Is (tadalafil and vardenafil) [775, 776]. However, some meta-analyses demonstrated that the combined use of SSRIs and PDE5Is may be more effective as compared with SSRIs or PDE5Is monotherapy [702, 777-781].

6.2.6.2.6 Other drugs

In addition to the aforementioned drugs, there is continuous research for other treatment options. Considering the abundant α1a-adrenergic receptors in seminal vesicles and the prostate, and the role of sympathetic system in the ejaculation physiology, the efficacy of selective α-blockers in the treatment of PE has been assessed [782-784]. A recent study demonstrated that wake-promoting agent modafinil may be effective in delaying ejaculation and improving PROMs [785]. The efficacy of acupuncture was compared to dapoxetine for the treatment of PE and although acupuncture showed a significant ejaculation-delaying effect, this was less effective as compared with that of dapoxetine [786].

Decreasing penile sensitivity with glans penis augmentation using hyaluronic acid for the treatment of PE has initially been proposed by Korean researchers in 2004 [787], and since then has gained popularity mainly in Asian countries [788, 789]. In a randomised controlled cross-over study, hyaluronic acid glans injection were found to be a safe treatment with a modest but significant increase in IELT [790]. However, these procedures may result in serious complications and more safety studies must be conducted before recommending this treatment to PE patients [791].

Considering the importance of central oxytocin receptors in ejaculation reflex, several researchers assessed the efficacy and safety of oxytocin receptor antagonists in the treatment of PE [792]. Epelsiban [793] and cligosiban [794-796] have been found to be safe and mildly effective in delaying ejaculation, but further controlled trials are needed [796].

*6.2.7 **Summary of evidence on the epidemiology/aetiology/pathophysiology of PE***

Summary of evidence	**LE**
Pharmacotherapy includes either dapoxetine on-demand (an oral short-acting SSRI) and the eutectic lidocaine/prilocaine spray (a topical desensitising agent) that are the only approved treatments for PE, or other off-label antidepressants (daily/on-demand SSRIs and clomipramine).	1a

*6.2.8 **Recommendations for the treatment of PE***

Recommendations	**Strength rating**
Treat erectile dysfunction (ED), other sexual dysfunction or genitourinary infection (e.g., prostatitis) first.	Strong
Use either dapoxetine or the lidocaine/prilocaine spray as first-line treatments for lifelong premature ejaculation (PE).	Strong
Use off-label topical anaesthetic agents as a viable alternative to oral treatment with selective serotonin re-uptake inhibitor (SSRIs).	Strong
Use tramadol on-demand as a weak alternative to SSRIs.	Weak
Use PDE5Is alone or in combination with other therapies in patients with PE (without ED).	Stong
Use psychological/behavioural therapies in combination with pharmacological treatment in the management of acquired PE.	Weak

6.3 Retarded or Delayed Ejaculation

*6.3.1 **Definition and classification***

The American Psychiatric Association defines DE as requiring one of two symptoms as follows: marked delay, infrequency, or absence of ejaculation on 75-100% of occasions, that persists for at least six months, and which causes personal distress [671]. Delayed ejaculation is a medical and/or psychological condition that is not associated with other types of psychiatric diagnosis. This definition is paramount to understanding the psychologic implications and treatment strategies for DE.

*6.3.2 **Pathophysiology and risk factors***

The causes of DE can be psychological, organic (e.g. incomplete spinal cord lesion or iatrogenic penile nerve damage), or pharmacological (e.g. selective serotonin re-uptake inhibitors (SSRIs), antihypertensive drugs, or antipsychotics) (Table 20) [797, 798]. Although low testosterone levels has been considered as a risk factor in the past [53, 650], more contemporary studies did not confirm any association between ejaculation times and serum testosterone levels [799, 800].

Table 20: Etiological Causes of Delayed Ejaculation and Anejaculation [801]

Ageing Male	Degeneration of penile afferent nerves inhibited ejaculation
Congenital	Mullerian duct cyst Wolfian duct abnormalities Prune Belly Syndrome Imperforate Anus Genetic abnormalities
Anatomic causes	Transurethral resection of prostate Bladder neck incision Circumcision Ejaculatory duct obstruction (can be congenital or acquired)
Neurogenic causes	Diabetic autonomic neuropathy Multiple sclerosis Spinal cord injury Radical prostatectomy Proctocolectomy Bilateral sympathectomy Abdominal aortic aneurysmectomy Para-aortic lymphadenectomy
Infective/Inflammation	Urethritis Genitourinary tuberculosis Schistosomiasis Prostatitis Orchitis
Endocrine	Hypogonadism Hypothyroidism Prolactin disorders
Medication	Antihypertensives; thiazide diuretics Alpha-adrenergic blockers Antipsychotics and antidepressants Alcohol Antiandrogens Ganglion blockers Selective serotonin reuptake Inhibitors
Psychological	Acute psychological distress Relationship distress Psychosexual skill deficit Disconnect between arousal and sexual situations Masturbation style

*6.3.3 **Investigation and treatment***

Patients should have a full medical and sexual history performed along with a detailed physical examination when evaluating for DE. It is not uncommon for clinicians to feel uncomfortable with the level of sexual

information that is warranted in obtaining a full sexual history. Understanding the details of the ejaculatory response, sensation, frequency, and sexual activity/techniques; cultural context and history of the disorder; the quality of the sexual response cycle (desire, arousal, ejaculation, orgasm, and refractory period); the partners' assessment of the disorder and if the partner suffers from any sexual dysfunction her/himself; and the overall satisfaction of the sexual relationship are all important to garner during history taking [802]. Investigation by a sexual therapist is often required to help get a complete psychological evaluation. It is incumbent on the clinician to diagnose medical pathologies that cause or contribute to DE, such as assessing the hormonal milieu, anatomy, and overall medical condition. Good communication between the sexual therapist and medical practitioner is vital to successful diagnosis and treatment of DE.

6.3.3.1 Psychological aspects and intervention

There is scarce literature on the psychological aspects relating to DE, as well as on empirical evidence regarding psychological treatment efficacy. Findings on psychological aspects revealed that men with DE showed a strong need for controlling their sexual experiences. Delayed ejaculation was associated with difficulties surrendering to sexual pleasure during sex, i.e., the sense of *letting go* [803], which denotes a psychological underlying mechanism influencing the reaching of orgasm [804]. As for psychological treatments, these may include, but are not limited to: increased genital-specific stimulation; sexual education; role-playing on his own and in front of his partner; retraining masturbatory practices; anxiety reduction on ejaculation and performance; and, re-calibrating the mismatch of sexual fantasies with arousal (such as with pornography use and fantasy stimulation compared to reality) [802]. A basic understanding of the sexual cycle for their respective partners can assist men and women in managing expectations and in evaluating their own sexual practices. Masturbation techniques that are either solo or partnered can be considered practice for the "real performance" which can eventually result in greater psychosexual arousal and orgasm for both parties [192]. Although masturbation with fantasy can be harmful when not associated with appropriate sexual arousal and context, fantasy can be quite supportive if it allows blockage of critical thoughts that may be preventing orgasm and ejaculation. Techniques geared towards reduction of anxiety are important skills that can help overcome the performance anxiety as this can often interrupt the natural erectile through orgasmic progression. Referral to a sexual therapist, psychiatrist or psychologist is appropriate and often warranted.

6.3.3.2 Pharmacotherapy

Pharmacologic agents have been used to treat DE with varied success. Unfortunately, there is no FDA or EMA approved medications to treat DE, as most of the cited research is based on case-cohort studies that have not been randomised, blinded, or placebo-controlled. Many drugs have been used as both primary treatments and/or as antidotes to other medications that can cause DE. A recent survey of sexual health providers demonstrated an overall treatment success of 40% with most providers commonly using cabergoline, bupropion, and oxytocin for treatments [805]. However, this survey measured the anecdotal results of practitioners and there was no proven efficacy or superiority of any drug due to a lack of placebo-controlled, randomised, blinded, comparative trials [801].

6.4 Anejaculation

*6.4.1 **Definition and classification***

Anejaculation involves the complete absence of antegrade or retrograde ejaculation. It is caused by failure of semen emission from the seminal vesicles, prostate, and ejaculatory ducts into the urethra [806]. True anejaculation is usually associated with a normal orgasmic sensation and is always associated with central or peripheral nervous system dysfunction or with drugs [807].

*6.4.2 **Pathophysiology and risk factors***

Generally, anejaculation shares the similar aetiologic factors with DE and retrograde ejaculation (see Table 20).

*6.4.3 **Investigation and treatment***

Drug treatment for anejaculation caused by lymphadenectomy and neuropathy, or psychosexual therapy for anorgasmia, is not very effective. In all these cases, and in men who have a spinal cord injury, vibro-stimulation (i.e., application of a vibrator to the penis) is the first-line therapy. In anejaculation, vibro-stimulation evokes the ejaculation reflex [808], which requires an intact lumbosacral spinal cord segment. If the quality of semen is poor, or ejaculation is retrograde, the couple may enter an *in-vitro* fertilisation program whenever fathering is desired. If vibro-stimulation has failed, electro-ejaculation can be the therapy of choice [809]. When electro-ejaculation fails or cannot be carried out, other sperm retrieval techniques may be used [810]. Anejaculation following either retroperitoneal surgery for testicular cancer or total mesorectal excision can be prevented using unilateral lymphadenectomy or autonomic nerve preservation [811], respectively.

6.5 Painful Ejaculation

*6.5.1 **Definition and classification***

Painful ejaculation is a condition where a patient feels mild discomfort to severe pain during or after ejaculation. The pain can involve the penis, scrotum, and perineum [812].

*6.5.2 **Pathophysiology and risk factors***

Many medical conditions can result in painful ejaculations, but it can also be an idiopathic problem. Initial reports demonstrated possible associations of painful ejaculation with calculi in the seminal vesicles [813], sexual neurasthenia [814], sexually transmitted diseases [812, 815], inflammation of the prostate [210, 816], PCa [817, 818], BPH [208], prostate surgery [819, 820], pelvic radiation [821], herniorrhaphy [822] and antidepressants [823-825], among others. Further case reports have suggested that mercury toxicity or Ciguatera toxin fish poisoning may also result in painful ejaculations [826, 827]. Psychological issues may also be the cause of painful ejaculations, especially if the patient does not experience this problem during masturbation [828].

*6.5.3 **Investigation and treatment***

Treatment of painful ejaculation must be tailored according to the underlying cause, if detected. Psychotherapy or relationship counselling, withdrawal of suspected agents (drugs, toxins, or radiation) [823, 824, 829] or the prescription of appropriate medical treatment (antibiotics, α-blockers, anti-inflammatory agents) may ameliorate painful ejaculations. Behavioural therapies, myorelaxants, antidepressant pelvic floor exercises, anticonvulsant drugs and/or opioids may be administered if no underlying cause can be identified [830, 831].

6.5.3.1 Surgical intervention

If medical treatments fail, surgical operations such as TURP, transurethral resection of the ejaculatory duct and neurolysis of the pudendal nerve have been suggested [832, 833]. However, there is no strong evidence supporting that surgical therapy improves painful ejaculations and therefore must be used with caution.

6.6 Retrograde ejaculation

*6.6.1 **Definition and classification***

Retrograde ejaculation is the total, or sometimes partial, absence of antegrade ejaculation, as a result of semen passing backwards through the bladder neck into the bladder. Patients may experience a normal, or decreased, orgasmic sensation. The causes of retrograde ejaculation can be divided into neurogenic, pharmacological, urethral, or bladder neck incompetence [812].

*6.6.2 **Pathophysiology and risk factors***

The process of ejaculation requires complex coordination and interplay between the epididymis, vas deferens, prostate, seminal vesicles, bladder neck and bulbourethral glands [834]. Upon ejaculation, sperm are rapidly conveyed along the vas deferens and into the urethra via the ejaculatory ducts. From there, the semen progresses in an antegrade fashion, in part maintained by coaptation of the bladder neck and rhythmic contractions of the periurethral muscles, coordinated by a centrally mediated reflex [834]. Closure of the bladder neck and seminal emission are initiated via the sympathetic nervous system from the lumbar sympathetic ganglia and subsequently hypogastric nerve. Prostatic and seminal vesicle secretion, as well as contraction of the bulbocavernosal, ischiocavernosal and pelvic floor are initiated by the S 2-4 parasympathetic nervous system via the pelvic nerve [834].

Any factor, which disrupts this reflex and inhibits the bladder neck (internal vesical sphincter) contraction may lead to retrograde passage of semen into the bladder. These can be broadly categorised as pharmacological, neurogenic, anatomic and endocrinal causes of retrograde ejaculation (Table 21).

Table 21: Aetiology of retrograde ejaculation [797]

Neurogenic	Spinal cord injury Cauda equina lesions Multiple Sclerosis Autonomic neuropathy Retroperitoneal lymphadenectomy Sympathectomy or aortoiliac surgery Prostate, colorectal and anal surgery Parkinson´s disease Diabetes mellitus Psychological/behavioural
Urethral	Ectopic ureterocele Urethral stricture Urethral valves or verumontaneum hyperplasia Congenital dopamine beta-hydroxylase deficiency
Pharmacological	Antihypertensives, thiazide diuretics Alpha-1-adrenoceptor antagonists Antipsychotics and antidepressants
Endocrine	Hypothyroidism Hypogonadism Hyperprolactinaemia
Bladder neck incompetence	Congenital defects/dysfunction of hemitrigone Bladder neck resection (transurethral resection of the prostate) Prostatectomy

*6.6.3 **Disease management***

Medical and surgical strategies exist for the treatment of retrograde ejaculation. In recent years the reliance on medical treatment as first-line management has become common practice.

6.6.3.1 Pharmacological

Sympathomimetics stimulate the release of noradrenaline as well as activating α- and β-adrenergic receptors, resulting in closure of the internal urethral sphincter, restoring the antegrade flow of semen. The most common sympathomimetics are synephrine, pseudoephedrine hydrochloride, ephedrine, phenylpropanolamine and midodrine [835]. Unfortunately, as time progresses their effect diminishes [836]. Many of the studies published about the efficacy of sympathomimetics in the treatment of retrograde ejaculation suffer from small sample size with some represented by case reports.

A double-blind controlled study randomised patients to one of four α-adrenergic agents (dextroamphetamine, ephedrine, phenylpropanolamine, and pseudoephedrine) with or without histamine. The patients suffered from the failure of ejaculation following retroperitoneal lymphadenectomy. They found that four days of treatment prior to ejaculation was most effective and that all the adrenergic agonists restored antegrade ejaculation [835]. In a SR, the efficacy of this group of medications was found to be 28% [197]. The side-effects of sympathomimetics include dryness of mucous membranes and hypertension.

The use of antimuscarinics has been described, including brompheniramine maleate and imipramine, as well as in combination with sympathomimetics. The calculated efficacy of antimuscarinics or antimuscarinics in combination with sympathomimetics are 22% versus 39%, respectively [197]. Combination therapy appears to be more effective although statistical analysis is not yet possible due to the small sample sizes.

6.6.3.2 Management of infertility

Infertility has been the major concern of patients with retrograde ejaculation. Beyond the use of standard sperm retrieval techniques, such as testicular sperm extraction (TESE), three different methods of sperm acquisition have been identified for the management of infertility in the patient suffering from retrograde ejaculation. These include; i) centrifugation and resuspension of post-ejaculatory urine specimens; ii) the Hotchkiss (or modified Hotchkiss) technique; and, iii) ejaculation on a full bladder.

1. *Centrifugation and resuspension.* In order to improve the ambient conditions for the sperm, the patient is asked to either increase their fluid intake or to take sodium bicarbonate to dilute or alkalise

the urine respectively. Afterwards, a post-orgasmic urine sample is collected by either introducing a catheter or spontaneous voiding. This sample is then centrifuged and suspended in a medium. The types of suspension fluids employed are heterogeneous and can include bovine serum albumin, human serum albumin, Earle's/Hank's, phosphate-buffered medium and the patients urine. The resultant modified sperm mixture can then be used in assisted reproductive techniques. A SR of the literature in couples with the male partner suffering from retrograde ejaculation found a 15% pregnancy rate per cycle (0-100%) [197].

2. *Hotchkiss method*. The Hotchkiss method involves emptying the bladder prior to ejaculation using a catheter and then washing out and instilling a small quantity of Lactated Ringers to improve the ambient conditions of the bladder. The patient then ejaculates, and semen is retrieved by catheterisation or voiding [837]. Modified Hotchkiss methods involve a variance in the instillation medium. Pregnancy rates per cycle were 24% per cycle (0-100%) [197].
3. *Ejaculation on a full bladder*. Few papers have described results from this technique [838, 839]. The patient is encouraged to ejaculate on a full bladder and semen is suspended in Baker's Buffer. The pregnancy rate in the two studies which included only five patients in total was 60% [197].

6.7 Anorgasmia

*6.7.1 **Definition and classification***

Anorgasmia is the perceived absence of orgasm and can give rise to anejaculation. Regardless of the presence of ejaculation, anorgasmia can be a lifelong (primary) or acquired (secondary) disorder [840].

*6.7.2 **Pathophysiology and risk factors***

Primary anorgasmia is defined as starting from the men's first sexual intercourse and lasts throughout his life, while for secondary anorgasmia patients should have a normal period before the problem starts [841]. Substance abuse, obesity and some non-specific psychological aspects, such as anxiety and fear, are considered the risk factors for anorgasmia. There are only a few studies available that describe anorgasmia alone and generally it has been considered as a symptom linked to ejaculatory disorders especially with DE and therefore they are believed to share the same risk factors. However, psychological factors are considered to be responsible for 90% of anorgasmia problems [842]. Causes of delayed orgasm and anorgasmia are shown in Table 22 [841].

Table 22: Causes of delayed orgasm and anorgasmia [841]

Endocrine	Testosterone deficiency Hypothyroidism
Medications	Antidepressants Antipsychotics Opioids
Psychosexual Causes	
Hyperstimulation	
Penile sensation loss	

*6.7.3 **Disease management***

The psychological/behavioural strategies for anorgasmia are similar for DE. The patient and his partner should be examined physically and psychosexually in detail including determining the onset of anorgasmia, medication and disease history, questioning penile sensitivity and psychological issues. Adjunctive laboratory tests can also be used to rule out organic causes, such as testosterone, prolactin and thyroid-stimulating hormone (TSH) levels. Patients who have loss of penile sensitivity require further investigations [841].

6.7.3.1 Psychological/behavioural strategies

Lifestyle changes can be recommended to affected individuals including: changing masturbation style; taking steps to improve intimacy; and, decreasing alcohol consumption. Several psychotherapy techniques or their combinations have been offered, including alterations in arousal methods, reduction of sexual anxiety, role-playing an exaggerated orgasm and increased genital stimulation [804, 843]. However, it is very difficult to determine the success rates from the literature.

6.7.3.2 Pharmacotherapy

Several drugs have been reported to reverse anorgasmia, including cyproheptadine, yohimbine, buspirone, amantadine and oxytocin [844-849]. However, these reports are generally from case-cohort studies and drugs

have limited efficacy and significant adverse effect profiles. Therefore current evidence is not strong enough to recommend drugs to treat anorgasmia.

6.7.3.3 Management of infertility

If patients fail the treatment methods mentioned above, penile vibratory stimulation, electro-ejaculation or TESE are the choice of options for sperm retrieval in anorgasmia cases [841].

6.8 Haemospermia

6.8.1 Definition and classification

Haemospermia is defined as the appearance of blood in the ejaculate. Although it is often regarded as a symptom of minor significance, blood in the ejaculate causes great anxiety in many men and may be indicative of underlying pathology [213].

6.8.2 Pathophysiology and risk factors

Several reasons of haemospermia have been acknowledged and can be classified into the following sub-categories; idiopathic, congenital malformations, inflammatory conditions, obstruction, malignancies, vascular abnormalities, iatrogenic/trauma and systemic causes (Table 23) [850].

Table 23: Pathology associated with haemospermia [850]

Category	Causes
Congenital	Seminal vesicle (SV) or ejaculatory duct cysts
Inflammatory	Urethritis, prostatitis, epididymitis, tuberculosis, CMV, HIV, Schistosomiasis, hydatid, condylomata of urethra and meatus, urinary tract infections
Obstruction	Prostatic, SV and ejaculatory duct calculi, post inflammatory, seminal vesicle diverticula/cyst, urethral stricture, utricle cyst, BPH
Tumours	Prostate, bladder, SV, urethra, testis, epididymis, melanoma
Vascular	Prostatic varices, prostatic telangiectasia, haemangioma, posterior urethral veins, excessive sex or masturbation
Trauma/ iatrogenic	Perineum, testicle, instrumentation, post hemorrhoid injection, prostate biopsy, vaso-venous fistula
Systemic	Hypertension, hemophilia, purpura, scurvy, bleeding disorders, chronic liver disease, renovascular disease, leukaemia, lymphoma, cirrhosis, amyloidosis
Idiopathic	-

The risk of any malignancy in patients presenting with haemospermia is approximately 3.5% (0-13.1) [851]. In an observational study of 300 consecutive patients over a 30-month period, 81% had no cause of their haemospermia identified. In those patients for whom a cause was identified, the diagnosis varied dependent upon the age of presentation. When the patients were divided into those under and those over 40 years of age, urinary tract infections were more common among younger patients compared to older patients (15% versus 10.3%). In the older group (> 40 years old), stones (2.2% versus 1.4%) and malignancy (6.2% versus 1.4%) were more common when compared with the younger cohort [60]. In the over 40 group, thirteen patients had PCa and one had a low-grade urethral carcinoma. In the under 40 group, one patient had testicular cancer [212].

6.8.3 Investigations

As with other clinical conditions, a systematic clinical history and assessment to help identify the reason of haemospermia is undertaken. Although the differential diagnosis is extensive, most cases are caused by infections or other inflammatory processes [213].

The basic examination of haemospermia should start with a thorough symptom-specific and systemic clinical history. The first step is to understand if the patient has true haemospermia. Pseudo-haemospermia may occur as a consequence of haematuria or even suction of a partner's blood into the urethra during copulation [812, 852, 853]. A sexual history should be taken to identify those whose haemospermia may be as a consequence of a sexually transmitted disease. Recent foreign travel to areas affected by schistosomiasis or tuberculosis should also be considered. The possibility of co-existing systemic disease such as hypertension, liver disease and coagulopathies should be investigated along with systemic features of malignancy such as weight loss, loss of appetite or bony pain. Examination of the patient should also include measurement of

the blood pressure, as there have been several case reports suggesting an association between uncontrolled hypertension and haemospermia [854, 855].

Most authors who propose an investigative baseline agree on the initial diagnostic tests, however, there is no consensus n this regard [850-852]. A urinalysis should be performed along with sending the urine for culture and sensitivities as well as microscopy. If tuberculosis or schistosomiasis is the suspected cause, the semen or prostatic secretions should be sent for analysis. A full sexually-transmitted disease screen including first void urine as well as serum and genitourinary samples should be taken and tested for *Chlamydia, Ureaplasma* and *Herpes*. Using this strategy, it may be possible to find an infectious agent among patients who would have been labelled as idiopathic haemospermia [856].

A serum PSA should be taken in men over the age of 40 years who have been appropriately counselled [214]. Blood work including a full blood count, liver function tests, and a clotting screen should be taken to identify systemic diseases. The question of whether further investigation is warranted depends on clinician judgment, patient age and an assessment of risk factors [850]. Digital rectal examination should also be performed and the meatus re-examined after DRE for the presence of bloody discharge [857]. Detection of a palpable nodule in the prostate is of importance as an association between haemospermia and PCa has been postulated although not completely proven.

Magnetic Resonance Imaging is being increasingly used as a definitive means to investigate haemospermia. The multiplanar ability of MRI to accurately represent structural changes in the prostate, seminal vesicles, ampulla of vas deferens, and ejaculatory duct has enabled the modality to be particularly useful in determining the origin of midline or paramedian prostatic cysts and in determining optimal surgical management [858]. The addition of an endorectal coil can improve the diagnostic accuracy for identifying the site and case of haemorrhage [859].

The use of cystoscopy has been included in the majority of suggested investigation protocols in patients with high-risk features (patients who are refractory to conservative treatments and patients with persistent haemospermia). It can provide invaluable information as it allows direct visualisation of the main structures in the urinary tract that can be attributed to causes of haemospermia such as although not limited to; polyps, urethritis, prostatic cysts, foreign bodies, calcifications and vascular abnormalities [860, 861].

With the advancement of optics, the ability to create ureteroscopes of diameters small enough to allow insertion into the ejaculatory duct and seminal vesicles has been made possible [862]. In a prospective study of 106 patients with prolonged haemospermia patients underwent both transrectal US and seminal vesiculoscopy. With both modalities combined, diagnoses were made in 87.7% of patients. When compared, head-to-head, the diagnostic yield for TRUS versus seminal vesiculoscopy was 45.3% versus 74.5%, respectively ($p < 0.001$) [863].

Melanospermia that is a consequence of malignant melanoma involving the genitourinary tract is a very rare condition and has also been described in two case reports [864, 865]. Chromatography of the semen sample can be used to distinguish the two by identifying the presence of melanin if needed.

6.8.4 ***Disease management***

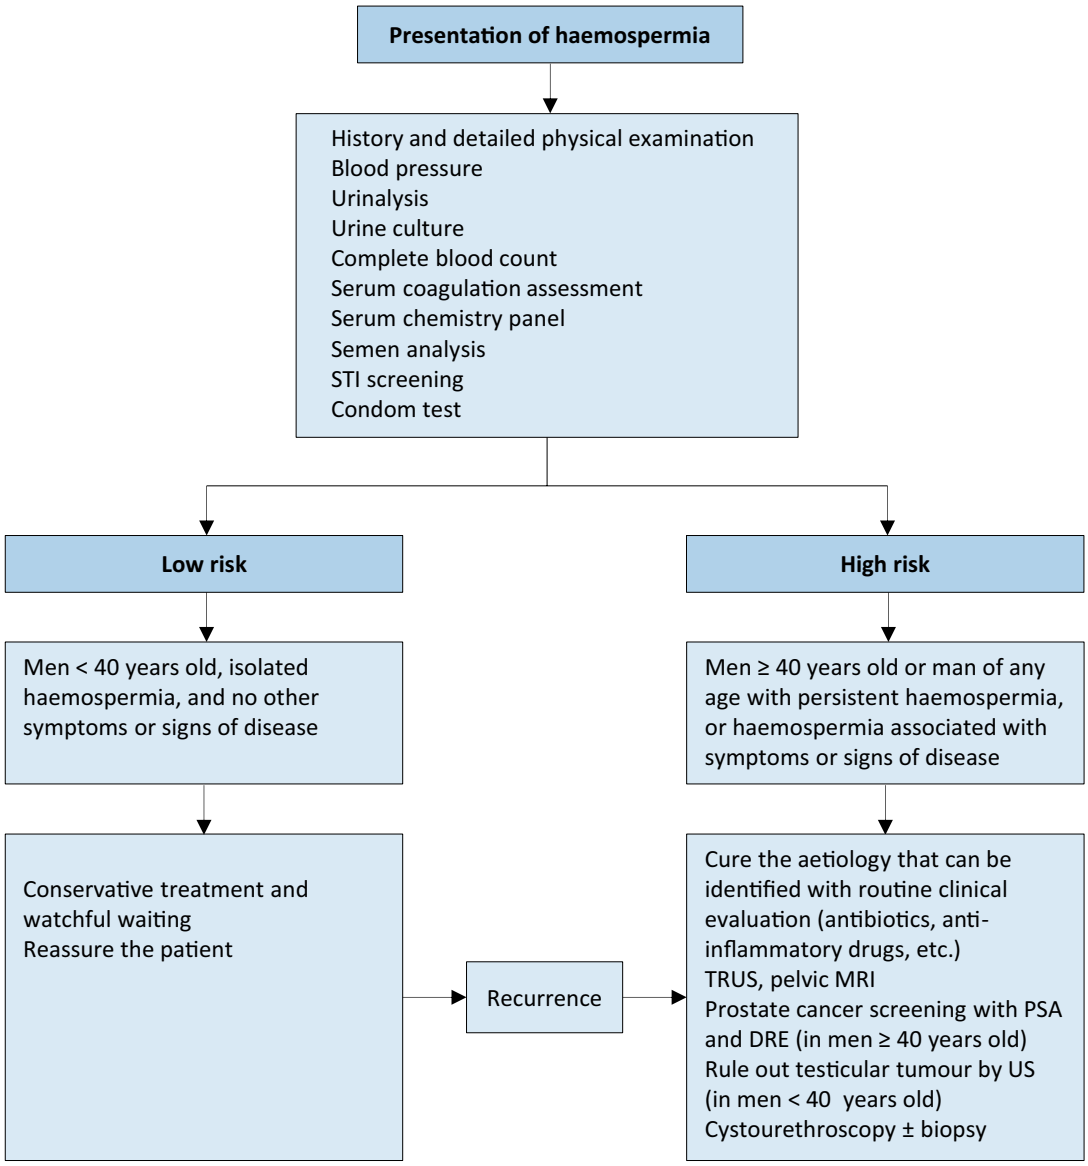
Conservative management is generally the primary treatment option when the patients are younger than 40 years of age and have a single episode of haemospermia. The primary goal of the treatment is to exclude malignant conditions like prostate and bladder cancer and treat any other underlying cause. If no pathology is found, then the patient can be reassured [213, 850].

Patients with recurrent haemospermia and who are middle-aged, warrant more aggressive intervention. Appropriate antibiotic therapy should be given to patients who have urogenital infections or STIs. Urethral or prostate varices or angiodyplastic vessels can be fulgurated, whereas cysts, either of the seminal vesicles or prostatic urethra, can be aspirated transrectally [213]. Ejaculatory duct obstruction is managed by a transurethral incision at the duct opening [866, 867]. Systemic conditions should be treated appropriately [851, 853, 868, 869].

Defining a management algorithm for haemospermia is based on the patient age and degree of haemospermia. Patients will often find the presence of blood in the ejaculate alarming, and investigations should be aimed at excluding a serious, despite infrequent, underlying cause (e.g., cancer), whilst at the same time preventing over investigation and alleviating patient anxiety. The literature describes a multitude of causes for haemospermia, although many of these pathologies are not commonly found after investigations have been

undertaken. However, men may be stratified into higher risk groups according to a number of factors including: men over 40 years of age, recurrent or persistent haemospermia, actual risk for PCa (e.g., positive family history), and concurrent haematuria. Based upon the literature, a management algorithm is proposed (Figure 9) [851, 853, 868, 869].

Figure 9: Management algorithm for haemospermia [851, 853, 868, 869]



STI = Sexually transmitted infections; PSA = Prostate specific antigen; DRE = Digital rectal examination; US = Ultrasonography; TRUS = Transrectal ultrasonography; MRI = Magnetic resonance imaging.

6.9 Recommendations for the management of recurrent haemospermia

Recommendations	Strength rating
Perform a full medical and sexual history with detailed physical examination.	Strong
Men ≥ 40 years of age with persistent haemospermia should be screened for prostate cancer.	Weak
Consider non-invasive imaging modalities (TRUS, MRI) in men ≥ 40 years of age or men of any age with persistent or refractory heamospermia.	Weak
Consider invasive methods such as cystoscopy and vesiculoscopy when the non-invasive methods are inconclusive.	Weak

7. LOW SEXUAL DESIRE AND MALE HYPOACTIVE SEXUAL DESIRE DISORDER

7.1 Definition and classification

It has been always a challenge to define sexual desire properly because it has a complicated nature and it can be conceptualised in many different ways. According to the ICD-10, lack or loss of sexual desire should be the principal problem and no other sexual problems accompanying it such as ED [870]. In the DSM-V, male hypoactive sexual desire disorder was defined as "the persistent or recurrent deficiency (or absence) of sexual or erotic thoughts or fantasies and desire for sexual activity". The judgment of deficiency is made by the clinician, taking into account factors that affect sexual functioning, such as age and general and socio-cultural contexts of the individual's life [671]. According to the fourth International Consultation on Sexual Medicine, the definition of male hypoactive sexual desire disorder was proposed as a "persistent or recurrent deficiency or absence of sexual or erotic thoughts or fantasies and desire for sexual activity (clinical principle)" [871].

7.2 Pathophysiology and risk factors

Several aetiological factors are considered to contribute to the pathophysiology of LSD. Levine proposed three components of sexual desire as drive (biological), motivation (psychological) and wish (cultural) [872]. However, it is believed that both in the surveys and clinical practice those three components are usually found interwoven [873].

*7.2.1 **Psychological aspects***

The endorsement of negative thoughts during sexual intercourse (i.e., concerns about erection, lack of erotic thoughts, and restrictive attitudes toward sexuality) predicted LSD in men [874]. Furthermore, feeling shame during sexual intercourse, because of negative sexual thoughts (e.g., concern about achieving erection), characterised men with LSD as opposed to women with the same condition [875]. Psychological models testing the interplay role between biopsychosocial factors revealed that reduced male sexual desire was best predicted by negative thoughts and emotions during sex, more than general psychopathology symptoms or age [876-878]. Similarly, having a low confidence achieving erection, no attraction toward the partner, living in long-term relationships, and stress resulting from work were predictors of LSD in men [879]. On the other hand, relationship factors such as marital satisfaction, cohesion or display of affection received little support [874, 879]. Even so, it is worth noting that, despite LSD being less common in men than in women [871], it is the most frequent complaint in couples' therapy [880]. Therefore, the role of relationship factors cannot be completely ruled out. In addition, anxiety proneness has been associated with LSD in men and is expected to shift men's attention from erotic cues to worrying thoughts, thereby decreasing sexual desire [881].

*7.2.2 **Biological aspects***

Testosterone seems to be essential for a man's sexual desire; however, sexual desire does not directly relate with the circulating level of testosterone, especially in older men [882]. The biological and psychology components that take place in the pathophysiology of LSD are shown in Table 24 [873, 883]. In addition to these factors, there have been some speculations on the role of thyroid and oxytocin hormones [634, 884].

Table 24: The list of common causes of low sexual desire in men [873, 883]

Androgen deficiency
Hyperprolactinaemia
Anger and anxiety
Depression
Relationship conflict
Stroke
Antidepressant therapy
Epilepsy
Post-traumatic stress syndrome
Renal failure
Coronary disease and heart failure
Ageing
HIV
Body-building and eating disorders
Erectile dysfunction
Prostatitis/chronic pelvic pain syndrome

*7.2.3 **Risk factors***

In an international survey aimed at estimating the prevalence and correlates of sexual problems in 13,882 women and 13,618 men from 29 countries (Global Study of Sexual Attitudes and Behaviours), risk factors for male LSD were age between 60-69 and 70-80 years, poor overall health, vascular diseases, being a current smoker, belief that aging reduces sex, divorce in the past three years, financial problems in the last three years, major depression, being worried about the future of relation and less than one sexual relation in a week [188].

7.3 Diagnostic work-up

*7.3.1 **Assessment questionnaires***

Sexual Desire Inventory (SDI) is a scale aimed at evaluating different components influencing the development and expression of sexual desire [885]. This self-administered questionnaire consists of fourteen questions which weigh the strength, frequency, and significance of an individual's desire for sexual activity with others and by themselves. The SDI suggests that desire can be split into two categories: dyadic and solitary desire. While dyadic desire refers to "interest in or a wish to engage in sexual activity with another person and desire for sharing and intimacy with another", solitary desire refers to "an interest in engaging in sexual behaviour by oneself, and may involve a wish to refrain from intimacy and sharing with others" [885].

*7.3.2 **Physical examination and investigations***

Similar to other forms of sexual dysfunctions, a thorough medical and sexual history must be obtained from men who complain of LSD. The depressive symptoms of the patients must be assessed [886] and relationship problems (e.g., conflict with the sexual partner) must be questioned. In the presence of accompanying symptoms suggestive of endocrinological problems, circulating total testosterone [887], prolactin [888] and thyroid hormones [634] levels can be evaluated.

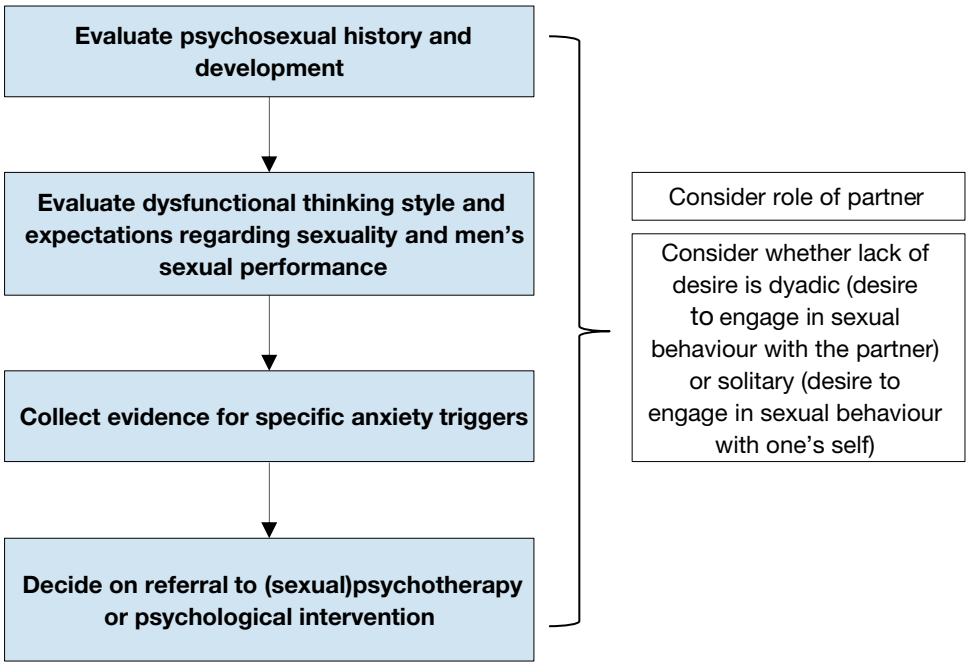
7.4 Disease management

The treatment of LSD should be tailored according to the underlying aetiology.

*7.4.1 **Psychological intervention***

Data on treatment efficacy ot psychological interventions are scarce. Accordingly, recommendations must be interpreted with caution. Psychological interventions with a focus on cognitive and behavioural strategies may be beneficial for LSD in men (Figure 10) [406]. Since both members of a couple may experience age-related changes concurrently and interdependently, it could be helpful to address the sexual health needs of the aging couple (thus including LSD) as a whole rather than treating the individual patient [889].

Figure 10: Flow-diagram of psychological evaluation of patients with low sexual desire



7.4.2 ***Pharmacotherapy***

Low sexual desire secondary to low testosterone levels can be treated with different formulations of testosterone administrations. The favourable effect of testosterone treatment on sexual motivation and the presence of sexual thoughts was shown in a meta-analysis [887]. The aim of the treatment should be to reach the physiological range of testosterone (see section 3.5).

Hyperprolactinaemia can also cause LSD and one of the most relevant aetiological factors is prolactin secreting pituitary adenomas. These adenomas can be easily diagnosed with MRI of the pituitary gland and can be treated with dopamine agonist agents [890]. The other accompanying endocrine disorders, such as hypothyroidism, hyperthyroidism or diabetes, should be treated accordingly.

Pharmacotherapy can also be used to treat major depression; however it should be kept in mind that antidepressants may negatively impact on sexual functioning; therefore, antidepressant compounds which have less effect on sexual function should be chosen. Psychotherapy can increase the efficacy of pharmacotherapy, especially for patients whose LSD is due to depression [891].

7.5 Recommendations for the treatment of low sexual desire

Recommendations	Strength rating
Perform the diagnosis and classification of low sexual desire (LSD) based on medical and sexual history, which could include validated questionnaires.	Weak
Include physical examination in the initial assessment of LSD to identify anatomical abnormalities that may be associated with LSD or other sexual dysfunctions, particularly erectile dysfunction.	Weak
Perform laboratory tests to rule out endocrine disorders.	Strong
Modulate chronic therapies which can negatively impact toward sexual desire.	Weak
Replace testosterone if LSD is associated with signs and symptoms of testosterone deficiency.	Strong

8. PENILE CURVATURE

8.1 Congenital penile curvature

8.1.1 Epidemiology/aetiology/pathophysiology

Congenital penile curvature (CPC) is a relatively rare condition, with a reported incidence of less than 1% [892], although there are studies which report higher prevalence rates of 4-10%, in the absence of hypospadias [893]. Congenital penile curvature results from disproportionate development of the tunica albuginea of the corporal bodies and is not associated with urethral malformation. In the majority of cases, the curvature is ventral, but it can also be lateral and, more rarely, dorsal [894].

8.1.2 Diagnostic evaluation

Taking a medical and sexual history is usually sufficient to establish a diagnosis of CPC. Patients usually present after reaching puberty as the curvature becomes more apparent with erections, and more severe curvatures can make intercourse difficult or impossible. Physical examination during erection (alternatively photographic or preferably after intracavernous injection (ICI) of vasoactive drugs) is important to document the curvature and exclude other pathologies [894].

8.1.3 Disease management

The definitive treatment for this disorder remains surgical and can be deferred until after puberty, although results from a survey suggest that men with probable untreated ventral penile curvature reported more dissatisfaction with penile appearance, increased difficulty with intercourse, and psychological problems, therefore supporting surgical correction of CPC in childhood [895]. Surgical treatments for CPC generally share the same principles as in Peyronie's disease. Plication techniques (Nesbit, 16-dot, Yachia, Essed-Schröeder, and others) with or without neurovascular bundle elevation (medial/lateral) and with or without complete penile degloving, have been described [896-905]. Other approaches are based on corporal body de-rotation proposed by Shaeer with different technical refinements that enable correction of a ventral curvature, with reported minimal narrowing and shortening [906-909]. There are no direct comparative studies therefore, no single technique can be advocated as superior in terms of surgical correction.

8.1.4 Summary of evidence for congenital penile curvature

Summary of evidence	LE
Medical and sexual history are usually sufficient to establish a diagnosis of CPC. Physical examination after ICI or a photograph during erection is mandatory for documentation of the curvature and exclusion of other pathologies.	3
There is no role for medical management of CPC. Surgery is the only treatment option, which can be deferred until after puberty and can be performed at any time in adult life in individuals with significant functional impairment during intercourse.	3

8.1.5 Recommendation for the treatment congenital penile curvature

Recommendation	Strength rating
Use plication techniques with or without neurovascular bundle dissection (medial/lateral) for satisfactory curvature correction, although there is currently no optimum surgical technique.	Strong

8.2 Peyronie's Disease

8.2.1 Epidemiology/aetiology/pathophysiology

8.2.1.1 Epidemiology

Epidemiological data on Peyronie's disease (PD) are limited. Prevalence rates of 0.4-20.3% have been published, with a higher prevalence in patients with ED and diabetes [910-918]. A recent survey indicates that the prevalence of definitive and probable cases of PD in the US is 0.7% and 11%, respectively, suggesting that PD is an under-diagnosed condition [919]. Peyronie's disease often occurs in older males with the typical age of onset of 50-60 years. However, PD also occurs in younger men (< 40 years), but at a lesser prevalence than older men (1.5 to 16.9%) [914, 920, 921].

8.2.1.2 Aetiology

The aetiology of PD is unknown. However, repetitive microvascular injury or trauma to the tunica albuginea is still the most widely accepted hypothesis to explain the aetiology of the disease [922]. Abnormal wound healing

leads to the remodeling of connective tissue into a fibrotic plaque [922-924]. Penile plaque formation can result in a curvature, which, if severe, may impair penetrative sexual intercourse. The genetic underpinnings of fibrotic diatheses, including PD and Dupuytren's diseases, are beginning to be understood (Table 25) [925].

Table 25: Genes with involvement in Peyronie's and Dupuytren's diseases (adapted from Herati *et al.* [925])

Gene	Gene Symbol	Chromosomal Location	Gene Function
Matrix metalloproteinase 2	MMP 2	16q12.2	Breakdown of extracellular matrix
Matrix metalloproteinase 9	MMP 9	20q13.12	Breakdown of extracellular matrix
Thymosin beta-10	TMSB-10	2p11.2	Prevents spontaneous globular actin monomer polymerisation
Thymosin beta-4	TMSB-4	Xq21.3-q22	Actin sequestering protein
Cortactin; amplaxin	CTTN	11q13	Organises cytoskeleton and cell adhesion structures
Transforming protein RhoA H12	RHOA	3p21.3	Regulates cytoskeletal dynamics
RhoGDP dissociation inhibitor	ARHGDIA	17q25.3	Regulates Rho GTPase signaling
Pleiotrophin precursors; osteoblast specific factor 1	PTN/OSF-1	7q33	Stimulates mitogenic growth of fibroblasts and osteoblasts
Amyloid A4 protein precursor; nexin II	PN-II	21q21.3	Cell surface receptor
Defender against cell death 1	DAD1	14q11.2	Prevents apoptosis
Heat Shock 27-kDa protein (HSP27)	HSP27	7q11.23	Actin organisation and translocation from cytoplasm to nucleus upon
Macrophage-specific stimulating factor	MCSF/CSF1	1p13.3	Controls the production, differentiation and function of macrophages
Transcription factor AP-1	AP1	1p32-p31	Key mediator of macrophage education and point of recruitment for immunosuppressive regulatory T cells
Human Early growth response protein 1	hEGR1	5q31.1	Promotes mitosis
Monocyte chemotactic protein 1	MCP1	17q11.2-q12	Chemotactic cytokine for monocytes and basophils
Bone Proteoglycan II precusor; Decorin	DCN	12q21.33	Matrix proteoglycan
T-Cell specific rantes protein precursor	RANTES	17q12	Chemoattractant for monocytes, memory T cells and eosinophils
Integrin Beta-1	ITGB1	10p11.2	Membrane receptor involved in cell adhesion and recognition in a variety of processes including immune response, tissue repair and hemostasis
Osteonectin	SPARC	5q31.3-q32	Matrix protein that facilitates collagen ossification
Ubiquitin	RBX1	6q25.2-q27	Targets substrate proteins for proteasomal degradation
Transcription factor ATF-4	ATF4	22q13.1	Transcriptional regulation of osteoblasts and down-regulates apelin to promote apoptosis
Elastase IIB	ELA2B	1p36.21	Serine protease that hydrolyzes matrix protein
c-myc	MYC	8q24.21	Transcription factor that regulates cell cycle progression, apoptosis, and cellular transformations
60 S ribosomal protein L13A	RPL13A	19q13.3	Repression of inflammatory genes

Prothymosin alpha	PTMA	2q37.1	Influences chromatin remodeling, anti-apoptotic factor
Fibroblast tropomyosin	TPM1	15q22.1	Actin-binding protein involved in contractile system of striated and smooth muscle
Myosin light chain	MYL2	12q24.11	Regulatory light chain associated with myosin Beta heavy chain
Filamin	FLN	Xq28	Actin-binding protein that crosslinks actin filaments and links actin to membrane glycoproteins. Interacts with integrins
Calcineurin A subunit alpha	PPP3CA	4q24	Promotes cell migration and invasion and inhibits apoptosis
DNA binding protein inhibitor Id-2	ID2	2p25	Transcriptional regulator that inhibits the function of basic helix-loop-helix transcription factors by preventing their heterodimerisation, negatively regulates cell differentiation
Smooth muscle gamma actin	ACTA2	10q23.3	Plays a role in cell motility, structure and integrity
Desmin	DES	2q35	Forms intra-cytoplasmic filamentous network connecting myofibrils
Cadherin FIB2	PCDHGB4	5q31	Cell adhesion proteins expressed in fibroblasts and playing a role in wound healing
Cadherin FIB1	DCHS1	11p15.4	Cell adhesion proteins expressed in fibroblasts and playing a role in wound healing
SMAD family member 7	SMAD7	18q21.1	Interacts with and promotes degradation of TGFBR1
Insulin-like growth factor binding protein 6	IGFBP6	12q13	Negative regulator of cellular senescence inhuman fibroblasts
Collagen 1 alpha	COL1A1	17q21.33	Encodes pro-alpha 1 chains of type 1 collagen
Transforming growth factor, beta 1	TGFB1	19q13.1	Cytokine that regulates proliferation, differentiation, adhesion and cell migration

8.2.1.3 Risk factors

The most commonly associated comorbidities and risk factors are diabetes, hypertension, dyslipidemias, ischaemic cardiopathy, autoimmune diseases [926], ED, smoking, excessive consumption of alcohol, low testosterone levels and pelvic surgery (e.g., radical prostatectomy) [343, 914, 918, 927-929]. Dupuytren's contracture is more common in patients with PD affecting 8.3-39% of patients [915, 930-932], whilst 4-26% of patients with Dupuytren's contracture report PD [931, 933].

8.2.1.4 Pathophysiology

Two phases of the disease can be distinguished [934]. The first is the active inflammatory phase (acute phase), which may be associated with painful erections and a palpable nodule or plaque in the tunica of the penis; typically, but not invariably, a penile curvature begins to develop. The second is the fibrotic phase (chronic phase) with the formation of hard, palpable plaques that can calcify, with stabilisation of the disease and of the penile deformity. With time, the penile curvature is expected to worsen in 21-48% of patients or stabilise in 36-67% of patients, while spontaneous improvement has been reported in only 3-13% of patients [927, 935-937]. Overall, penile deformity is the most common first symptom of PD (52-94%). Pain is the second most common presenting symptom of PD, which presents in 20-70% of patients during the early stages of the disease [938]. Pain tends to resolve with time in 90% of men, usually during the first twelve months after the onset of the disease [935, 936]. Palpable plaques were reported as initial symptom in 39% of the patients and mostly situated dorsally [48, 938].

In addition to functional effects on sexual intercourse, men may also suffer from significant psychological distress. Validated mental health questionnaires have shown that 48% of men with PD have moderate or severe depression, sufficient to warrant medical evaluation [939].

8.2.1.5 Summary of evidence on epidemiology/aetiology/pathophysiology of Peyronie's disease

Summary of evidence	LE
Peyronie's disease is a connective tissue disorder, characterised by the formation of a fibrotic lesion or plaque in the tunica albuginea, which may lead to penile deformity.	2b
The contribution of associated comorbidities or risk factors (e.g., diabetes, hypertension, lipid abnormalities and Dupuytren's contracture) to the pathophysiology of PD are still unclear.	3
Two phases of the disease can be distinguished. The first phase is the active inflammatory phase (acute phase-painful erections, nodule/plaque), and the second phase is the fibrotic/calcifying phase (chronic or stable phase) with formation of hard palpable plaques (disease stabilisation).	2b
Spontaneous resolution is uncommon (3-13%) and most patients experience disease progression (21-48%) or stabilisation (36-67%). Pain is usually present during the early stages of the disease, but tends to resolve with time in 90% of men within twelve months of onset.	2a

8.2.2 ***Diagnostic evaluation***

The aim of the initial evaluation is to obtain information on the presenting symptoms and their duration (e.g., pain on erection, palpable nodules, deformity, length and girth and erectile function). It is important to obtain information on the distress caused by the symptoms and the potential risk factors for ED and PD. A disease-specific questionnaire (Peyronie's disease questionnaire [PDQ]) has been developed to be used both in clinical practice and trials. Peyronie's disease questionnaire measures three domains, including psychological and physical symptoms, penile pain and symptom bother [940].

Clinicians should take a focused history to distinguish between active and stable disease, as this will influence medical treatment or the timing of surgery. Patients who are still likely to have active disease are those with a shorter symptom duration, pain on erection, or a recent change in penile deformity. Resolution of pain and stability of the curvature for at least three months are well-accepted criteria of disease stabilisation and patients' referral for specific medical therapy [941, 942] or surgical intervention when indicated [943].

The examination should start with a focused genital assessment which is then extended to the hands and feet for detecting possible Dupuytren's contracture or Ledderhosen scarring of the plantar fascia [936]. Penile examination is performed to assess the presence of a palpable nodule or plaque. There is no correlation between plaque size and the degree of curvature [944]. Measurement of the stretched or erect penile length is important because it may have an impact on the subsequent treatment decisions and potential medico-legal implications [945-947].

An objective assessment of penile curvature with an erection is mandatory. According to current literature, this can be obtained by several approaches, including a home (self) photography of a natural erection (preferably), using a vacuum-assisted erection test or an ICI using vasoactive agents. However, it has been suggested that the ICI method is superior, as it is able to induce an erection similar to or better than that which the patient would experience when sexually aroused [948-950]. Computerised Tomography and MRI have a limited role in diagnosis of the curvature and are not recommended on a routine basis. Erectile function can be assessed using validated instruments such as the IIEF although this has not been validated in PD patients [951]. Erectile dysfunction is common in patients with PD (30-70.6%) [952, 953]. It is mainly arterial or cavernosal (veno-occlusive) dysfunction in origin [927, 944, 954]. The presence of ED and psychological factors may also have a profound impact on the treatment strategy [953].

Ultrasound measurement of plaque size is inaccurate, and it is not recommended in everyday clinical practice [955]. Doppler US may be used for the assessment of penile haemodynamics [953].

8.2.2.1 Summary of evidence for the diagnosis of Peyronie's disease

Summary of evidence	LE
Ultrasound (US) measurement of the plaque's size is inaccurate and operator dependent.	3
Doppler US may be required for the assessment penile haemodynamic and vascular anatomy.	2a
Intracavernous injection method is superior to other methods to provide an objective assessment of penile curvature with an erection.	4

8.2.2.2 Recommendations for the diagnosis of Peyronie's disease

Recommendations	Strength rating
Take a medical and sexual history of patients with Peyronie's disease, include duration of the disease, pain on erection, penile deformity, difficulty in vaginal intromission due to disabling deformity and erectile dysfunction (ED).	Strong
Take a physical examination, including assessment of palpable plaques, stretched or erect penile length, degree of curvature (self-photography, vacuum-assisted erection test or pharmacological-induced erection) and any other related diseases (e.g. Dupuytren's contracture, Ledderhose disease) in patients with PD.	Strong
Use intracavernous injection (IC) method to provide an objective assessment of penile curvature with an erection in the diagnostic work-up of PD.	Weak
Use the Peyronie's disease specific questionnaire especially in clinical trials, but mainstream usage in daily clinical practice is not mandatory.	Weak
Do not use ultrasound, computerised tomography or magnetic resonance imaging to assess plaque size and deformity in everyday clinical practice.	Weak
Use Doppler US only in the case of diagnostic evaluation of ED, to ascertain penile haemodynamic and vascular anatomy.	Weak

8.2.3 ***Disease management***

8.2.3.1 Conservative treatment

Conservative treatment of PD is primarily focused on patients in the early stage of the disease as an adjunct treatment to relieve pain and prevent the progression of the disease or if the patient declines other treatment options during the active phase [936, 943]. Several options have been suggested, including oral pharmacotherapy, intralesional injection therapy, shock wave therapy (SWT) and other topical treatments (Table 26).

The results of the studies on conservative treatment for PD are often contradictory making it difficult to provide recommendations in the everyday, real-life setting [956]. The Panel does not support the use of oral treatments for PD including pentoxifylline, vitamin E, tamoxifen, procarbazine, potassium para-aminobenzoate (potaba), omega-3 fatty acids or combination of vitamin E and L-carnitine because of their lack of efficacy (tamoxifen, colchicine, vitamin E, procarbazine) or evidence (potaba, L-carnitine, pentoxyfilline) [943, 957-959]. This statement is based on several methodological flaws in the available studies. These include their uncontrolled nature, the limited number of patients treated, the short-term follow-up and the different outcome measures used [960, 961]. Even in the absence of adverse events, treatment with these agents may delay the use of other efficacious treatments.

Table 26: Conservative treatments for PD

Oral treatments
Non-steroidal anti-inflammatory drugs (NSAIDs)
Phosphodiesterase type 5 inhibitors (PDE5I)
Intralesional treatments
Verapamil
Nicardipine
Clostridium collagenase
Interferon α2B
Hyaluronic acid
Botulinum toxin
Topical treatments
H-100 gel
Extracorporeal shockwave treatment
Other
Traction devices
Multimodal treatment

8.2.3.1.1 Oral treatment

Phosphodiesterase type 5 inhibitors

Phosphodiesterase type 5 inhibitors were first suggested as a treatment for PD in 2003 to reduce collagen deposition and increase apoptosis through the inhibition of transforming growth factor (TGF)-b1 [962, 963]. A retrospective study of 65 men suggested the use of PDE5I as an alternative for the treatment of PD. The results indicated that treatment with tadalafil was helpful in decreasing curvature and remodelling septal scar when compared to controls [964]. Another recent study concluded that sildenafil was able to improve erectile function and pain in PD patients. In the study, 39 patients with PD were divided into two groups receiving vitamin E (400 IU) or sildenafil 50 mg for twelve weeks and significantly better outcomes in pain and IIEF score were seen in the sildenafil group [965].

Nonsteroidal anti-inflammatory drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs) may be offered to patients in active-phase PD in order to manage penile pain, which is usually present in this phase. Pain levels should be periodically reassessed in monitoring treatment efficacy.

8.2.3.1.2 Intralesional treatment

Injection of pharmacologically active agents directly into penile plaques represents another treatment option. It allows a localised delivery of a particular agent that provides higher concentrations of the drug inside the plaque. However, delivery of the compound to the target area is difficult to ensure, particularly when a dense or calcified plaque is present.

Calcium channel antagonists: verapamil and nicardipine

The rationale for intralesional use of channel antagonists in patients with PD is based on *in vitro* research [966, 967]. Due to the use of different dosing schedules and the contradictory results obtained in published studies, the evidence is not strong enough to support the clinical use of injected channel blockers verapamil and nicardipine and the results do not demonstrate a meaningful improvement in penile curvature compared to placebo [968-973]. In fact, most of the studies did not perform direct statistical comparison between groups.

Collagenase of clostridium histolyticum

Collagenase of *clostridium histolyticum* (CCH) is a chromatographically purified bacterial enzyme that selectively attacks collagen, which is known to be the primary component of the PD plaque [974-977]. Intralesional injection of CCH has been used in the treatment of PD since 1985. In 2014 the EMA approved CCH for the nonsurgical treatment of the stable phase of PD in men with palpable dorsal plaques in whom abnormal curvature of 30º to 90º and non-ventrally located plaques is present. It should be administered by a healthcare professional who is experienced and properly trained in the administration of CCH treatment for PD [978, 979].

The original treatment protocol in all studies consists of two injections of 0.58 mg of CCH 24-72 hours apart every six weeks for up to four cycles. Data from IMPRESS (Investigation for Maximal Peyronie´s Reduction Efficacy and Safety Studies) II and II studies [976], as well as post approval trials [980], which demonstrated the efficacy and safety of this treatment, are summarised in the Table 27.

Table 27: Clinical evidence supporting CCH treatment

Author/Year	Study type	Special considerations	Number of patients	Number of injections	Decrease in PC in CCH group
Gelbard *et al.* (2013) [981]	Phase 3 randomised double-blinded controlled trial	Pilot study	551	8 (in 78.8% of patients)	34% (17.0 ± 14.8 degrees)
Levine *et al.* (2015) [982]	Phase 3 open-label	IMPRESS based	347	≤ 8	34.4% (18.3 ± 14.02 degrees)
Ziegelmann *et al.* (2016) [983]	Prospective, double-blinded trial	IMPRESS based	69	Mean = 6	38% (22.6 ± 16.2 degrees)
Yang and Bennett (2016) [984]	Prospective study	Included patients in acute phase	37 in SP 12 in AP	Median in SP = 6 Median in AP = 2.5	32.4% (15.4 degrees) AP = 20 degrees
Nguyen *el al.* (2017) [951]	Retrospective study	Included patients in acute phase	126 in SP 36 in AP	Mean = 3.2	SP = 27,4% (15.2 ± 11.7 degrees) AP = 27,6% (18.5 ± 16.2 degrees) N/S differences in final change in curvature between group 1 (16.7º) and group 2 (15.6º) p=0.654
Anaissie *et al.* (2017) [985]	Retrospective study	Included patients in acute phase	77	Mean = 6.6	29.6% (15.3 ± 12.9 degrees)
Abdel Raheem *et al.* (2017) [986]	Prospective study	Shortened protocol	53	Mean = 3	31.4% (17.6 degrees)
Capece *et al.* (2018) [987]	Prospective multicentric study	Shortened protocol	135	Mean = 3	42.9% (19.1 degrees)

SP = Stable phase; AP = Acute phase; N/S = Non-significant.

The average improvement in curvature was 34% compared to 18.2% in the placebo group. Three adverse events of corporeal rupture were surgically repaired. The greatest chance of curvature improvement is for curvatures between 30° and 60°, longer duration of disease, an IIEF > 17, and no calcification [942]. An 18.2% improvement from baseline in the placebo arm was also observed. These findings raise questions regarding the alleged role of plaque injection and penile modeling, regardless of the medication, in improving outcomes in men with PD as the placebo or modeling arm resulted in a relatively high curvature reduction compared to treatment.

The conclusion of the IMPRESS I and II studies is that that CCH improves PD both physically and psychologically [981]. A post hoc meta-analyses of the IMPRESS studies demonstrated better results in patients with less than 60º of curvature, more than two years of evolution, no calcification in the plaque and good erectile function [980].

A relatively new modified short protocol which consists of the administration of a single (0.9 mg, one vial) injection per cycle distributed along three lines around the point of maximum curvature up to three cycles, separated by four-weekly intervals, has been proposed, and replaces the physician modelling with a multimodal approach through penile stretching, modelling and vacuum device at home [986]. The results from this modified protocol were comparable to the results of the IMPRESS trials and appear to decrease the

cost and duration of the treatment, although these represent non-randomised study protocols. These results were further explored in a prospective non-randomised multi-centric study [982]. In another large single-arm multi-centre clinical study using the shortened protocol, longer PD duration, greater baseline PC and basal and dorsal plaque location were identified as clinically significant predictors of treatment success [988]. Accordingly, a nomogram developed to predict treatment success after CCH for PD showed that patients with longer PD duration, greater baseline penile curvature and basal plaque location had a greater chance of treatment success [988]; however, these findings need to be externally validated.

Regarding safety concerns, the majority of PD's patients treated with CCH experienced at least one mild or moderate adverse reaction localised to the penis (penile haematoma (50.2%), penile pain (33.5%), penile swelling (28.9%) and injection site pain (24.1%)) which resolved spontaneously within fourteen days of the injection [989]. The adverse reaction profile was similar after each injection, regardless of the number of injections administered. Serious TEAE´s (0.9%) include penile haematoma and corporeal rupture that require surgical treatment. According to both IMPRESS' data and the shortened protocol, in order to prevent serious TEAE men should be advised to avoid sexual intercourse in the four weeks following the injection. Recent preliminary data suggest that treatment in the acute phase of the disease can be effective and safe [946, 979-981].

In conclusion, CCH is a safe and established treatment for active-phase disease; more recent evidence would suggest that CCH may also have a role in affecting the progression of active-phase disease, thus suggesting that the indications for CCH use could be expanded, although there is the possibility of a high placebo effect. It should also be noted that there is a large effect of traction or modelling in controlled studies, whilst studies reporting on modified protocols have small numbers of patients and are largely uncontrolled. Therefore, patients should be counselled fully on the efficacy of collagenase and the high cost of treatment.

It has been suggested that those patients with severe curvature may also benefit from CCH injections because of a potential downgrading of the penile curvature: a decrease in curvature may allow for a penile plication procedure instead of a plaque incision and grafting procedure, therefore avoiding the more negative impact on erectile function [986]. However, further investigation is needed to validate these initial findings [951, 984]. The panel has agreed to keep the whole set of information and recommendations regarding the use of CCH in men with PD despite the recent report about the official withdrawal of the product from the European market by the company.

Interferon α-2b

Interferon α-2b (IFN-α2b) has been shown to decrease fibroblast proliferation, extracellular matrix production and collagen production from fibroblasts and improve the wound healing process from PD plaques *in vitro* [990]. Intralesional injections (5x10^6 units of IFN-α2b in 10 mL saline every two weeks over twelve weeks for a total of six injections) significantly improved penile curvature, plaque size and density, and pain compared to placebo. Additionally, penile blood flow parameters benefited in the IFN-α2b group [979, 991, 992]. A study showed that regardless of plaque location, IFN-α2b is an effective treatment option. Treatment with IFN-α2b provided a greater than 20% reduction in curvature in the majority of men with PD, independent of plaque location [993]. Given the mild side-effects, which include sinusitis and flu-like symptoms, which can be effectively treated with NSAIDs drugs before IFN-α2b injection, and the moderate strength of data available, IFN-α2b is currently recommended for treatment of stable-phase PD.

Steroids, hyaluronic Acid and Botulinum toxin (botox)

In the only single-blind, placebo-controlled study with intralesional administration of betamethasone, no statistically significant changes in penile deformity, penile plaque size, and penile pain during erection were reported [994]. Adverse effects include tissue atrophy, thinning of the skin and immunosuppression [995]. Only a case-controlled single site study and a prospective non-controlled study support the use of hyaluronic acid injections in PD, with conflicting results related to penile curvature or penile pain [996, 997]. As only a single study evaluated intralesional botox injections in men with PD, the panel conclude that there is no robust evidence available to support these treatments [998].

8.2.3.1.3 Topical treatments

Topical verapamil and H-100 Gel

There is no sufficient and unequivocal evidence that topical treatments (neither verapamil, H-100 Gel [a compound with nicardipine, superoxide dismutase and emu oil] nor steroids) applied to the penile shaft, with or without the use of iontophoresis (now known as transdermal electromotive drug administration [EMDA]), result in adequate levels of the active compound within the tunica albuginea [999-1002]. Therefore, the panel does not support the use of topical treatments for PD applied to the penile shaft.

Extracorporeal shockwave treatment

The mechanical shear stress provoked by low-intensity extracorporeal shockwave treatment (LI-ESWT) on the treated tissue was deemed to induce neovascularisation and to enhance local blood flow [956]. The mechanism of action involved in ESWT for PD is still unclear, but there are two hypotheses. In the first hypothesis, shockwave therapy works by directly damaging and remodeling the penile plaque. In the second hypothesis, shockwave lithotripsy increases the vascularity of the area by generating thermodynamic changes resulting in an inflammatory reaction, with increased macrophage activity causing plaque lysis and eventually leading to plaque resorption [1003, 1004].

Four RCTs and one meta-analysis [1005-1009] assessed the efficacy of ESWT in the treatment of PD. Three were sham-controlled trials while one compared ESWT with the combination of ESWT and PDE5I (tadalafil) [1007].

All trials showed positive findings in terms of pain relief, but no effect on penile curvature and plaque size. Inclusion criteria varied widely among studies and further investigation is needed. The results are summarised in the Table 28.

Table 28: Efficacy of ESWT in the treatment of PD

Author/Year	Nº cases/ controls	Inclusion criteria	Comparator	Follow up	Protocol of treatment	Results	AES´s
Palmieri *et al.* 2009 [1005]	50 / 50	PD <12 mo. No previous treatment	Sham therapy	6 month	1 session/week x 4 weeks 2000 sw, 0.25 mJ/mm^2, 4 Hz	**Change in IIEF** (+5.4points) **Pain reduction** (-5.1 points) **Change in curvature** (-1.4º) **Plaque size** (-0.6 in)	No
Chitale *et al.* 2010 [1006]	16 / 20	Stable PD > 6 mo. No previous treatment	Sham therapy	6 month	1 session/week x 6 weeks. No other parameters mentioned.	**Change in IIEF** N/S **Pain reduction** N/S **Change in curvature** N/S **Plaque size** N/S	No
Palmieri *et al.* 2011 [1007]	50 / 50	PD <12 mo. Painful erections Presence of ED	ESWT + tadalafil 5 mg OD	6 month	1 session/week x 4 weeks 2000 sw, 0.25 mJ/mm^2, 4 Hz	**Change in IIEF** Significant in both groups **Pain reduction** Significant in both groups **Change in curvature** N/S **Plaque size** N/S	No
Hatzichristodoulou *et al.* 2013 [1008]	51 / 51	Stable PD > 3 mo. Previous unsuccessful oral treatment	Sham therapy	1 month	1 session/week x 6 weeks 2000 sw, 0.29 mJ/mm^2	**Change in IIEF** N/A **Pain reduction** (-2.5 points **Change in curvature** N/S **Plaque size** N/S	Ecchymosis 4,9%

N/A = no assessed; N/S = no significant; IIEF = International index of erectile function; VAS = Visual Analogic Scale; ED = Erectile dysfunction

Penile traction therapy

In men with PD, potential mechanisms for disease modification with penile traction therapy (PTT) have been described, including collagen remodelling via decreased myofibroblast activity and matrix metalloproteinase up-regulation [1010, 1011].

The stated clinical goals of PTT are to non-surgically reduce curvature, enhance girth, and recover lost length,

which are very attractive to patients suffering from PD. However clinical evidence is limited due to the limited number of patients included (267 in total), the heterogeneity in the study designs, and the non-standardised inclusion and exclusion criteria make it impossible to draw any definitive conclusions about this therapy [1012-1016].

Most of the included patients will need further treatment to ameliorate their curvature for satisfactory sexual intercourse. Moreover, the effect of PTT therapy in patients with calcified plaques, hourglass of hinge deformities which are, theoretically, less likely to respond to PTT has not been systematically studied. In addition, the treatment can result in discomfort and be inconvenient due to use of the device for an extended period (two to eight hours daily), but has been shown to be tolerated by highly motivated patients. There were no serious adverse effects, including skin changes, ulcerations, hypoesthesia or diminished rigidity [1014, 1017].

In conclusion, PTT seems to be effective and safe for patients with PD, but there is still lack of evidence to give any definitive recommendation in terms of monotherapy for PD.

Table 29: Summary of clinical evidence of PTT as monotherapy

Author/Year	Study type	Device	Number of patients	Hours of use	Result
Levine *et al.* (2008)	Pilot Prospective, uncontrolled	Fast Size®	10	2-8h 6 months	Mean reduction in PC 33% (51°-34°) SPL: + 0.5-2 cm EG: + 0.5-1 cm IIEF: + 5.3

NIG = non-intervention group; IIEF = International Index of Erectile Function; N/S = Not Significant; PD = Peyronie´s Disease; AP = Acute phase; CP = Chronic phase; SPL - Stretched penile length; EG = Erect girth, mo = month.

Vacuum erection device

Vacuum erection device (VED) therapy results in dilation of cavernous sinuses, decreased retrograde venous blood flow and increased arterial inflow [1018]. Intracorporeal molecular markers are affected by VED application, including decreases in hypoxia-inducible factor-1a, transforming growth factor (TGF)-b1, collagenase, and apoptosis, and increases endothelial nitric oxide synthase and a-smooth muscle actin, given a role in the pathogenesis of PD [1019]. Only one clinical study assessed the efficacy of VED therapy in mechanically straightening the penile curvature of PD as monotherapy and further investigation is needed [1020].

8.2.3.1.4 Multimodal treatment

There is some data suggesting that a combination of different oral drugs can be used in the treatment of the acute phase of PD. However, there does not seem to be a consensus on which drugs to combine, the optimum drug dosage; nor has there been a comparison of different drug combinations.

A long-term study assessing the role of multimodal medical therapy (injectable verapamil associated with antioxidants and local diclofenac) demonstrated that it is efficacious to treat PD patients. The authors concluded that combination therapy reduced pain more effectively than verapamil alone, making this specific combination treatment more effective compared to monotherapy [1019]. Furthermore, combination protocols including injectable therapies, such as CCH, have been studied in controlled trials. The addition of adjunctive PTT and VED have been described, however, limited data is available regarding its use [1021].

Penile traction therapy was evaluated as an adjunctive therapy to intralesional injections with interferon, verapamil, or CCH [969, 1022, 1023]. Results from these studies have failed to demonstrate statistically significant improvements in penile length or curvature, with the exception of one subset analysis identifying a 0.4 cm length increase among men using the devices for > 3 hours a day [1023]. A meta-analysis comparing the efficacy of PTT as an adjuvant treatment demonstrated that men who used PTT as an adjunct treatment to surgery or injection therapy in the treatment of PD had, on average, an increase in stretched penile length (SPL) of 1 cm compared to men who did not use adjunct PTT. There was no significant change in curvature between the two groups [1024].

Data available on the combined treatment of CCH and the use of VED between injection intervals reported statistically significant mean improvements in curvature (-17º) and penile length (+0.4 cm) after treatment. However, it is not possible to determine the isolated effect of VED because of a lack of control groups [986, 1024].

Recent data suggested that the combination of PDE5I (sildenafil 25 mg twice a day) after CCH treatment (shortened protocol combined with VED) is superior to CCH alone for improving penile curvature and erectile function. Further studies are necessary to externally validate those findings.

8.2.3.1.5 Summary of evidence for conservative treatment of Peyronie's disease

Summary of evidence	**LE**
Conservative treatment for PD is primarily aimed at treating patients in the early stage of the disease in order to relieve symptoms and prevent progression.	3c
There is no convincing evidence supporting oral treatment with acetyl esters of carnitine, vitamin E, potassium para-aminobenzoate (potaba) and pentoxifylline.	3c
Due to adverse effects, treatment with oral tamoxifen is no longer recommended.	3c
Nonsteroidal anti-inflammatory drugs can be used to treat pain in the acute phase.	5
Intralesional treatment with calcium channel antagonists: verapamil and nicardipine are no longer recommended due to contradictory results.	1b
Intralesional treatment with collagenase of *clostridium histolyticum* showed significant decreases in penile curvature, plaque diameter and plaque length in men with stable disease.	1b
Intralesional treatment with interferon may improve penile curvature, plaque size and density, and pain.	2b
Intralesional treatment with steroids are no longer recommended due to adverse effects include tissue atrophy, thinning of the skin and immunosuppression.	3c
No robust evidence is available to support treatment with intralesional hyaluronic acid or botulinum toxin.	3c
There is no evidence that topical treatments applied to the penile shaft result in adequate levels of the active compound within the tunica albuginea.	3c
The use of iontophoresis is not recommended due to the absence of efficacy data.	3c
Extracorporeal shockwave treatment may be offered to treat penile pain, but it does not improve penile curvature and plaque size.	2b
Treatment with penile traction therapy alone or in combination with injectable therapy as part of a multimodal approach may reduce penile curvature and increase penile length, although studies have limitations.	3c

8.2.3.1.6 Recommendations for non-operative treatment of Peyronie's disease

Recommendations	Strength rating
Offer conservative treatment to patients not fit for surgery or when surgery is not acceptable to the patient.	Strong
Discuss with patients all the available treatment options and expected results before starting any treatment.	Strong
Do not offer oral treatment with vitamin E, potassium para-aminobenzoate (potaba), tamoxifen, pentoxifiline, colchicine and acetyl esters of carnitine to treat Peyronie's disease (PD).	Strong
Nonsteroidal anti-inflammatory drugs (NSAIDs) can be used to treat penile pain in the acute phase of PD.	Strong
Extracorporeal shockwave treatment (ESWT) can be used to treat penile pain in the acute phase of PD.	Weak
Phosphodiesterase type 5 inhibitors can be used to treat concomitant erectile dysfunction or if the deformity results in difficulty in penetrative intercourse in order to optimise penetration.	Weak
Intralesional therapy with interferon alpha-2b may be offered in patients with stable curvature dorsal or lateral > 30º seeking a minimal invasive procedure.	Strong
Intralesional therapy with collagenase *clostridium histolyticum* may be offered in patients with stable PD and dorsal or lateral curvature > 30º, who request non-surgical treatment, although the placebo effects are high.	Strong
Do not offer intralesional treatment with steroids to reduce penile curvature, plaque size or pain.	Strong
Do not offer ESWT to improve penile curvature and reduce plaque size.	Strong
Penile traction devices and vacuum devices may be offered to reduce penile deformity or as part of a multimodal therapy approach, although outcome data is limited.	Weak

8.2.3.2 Surgical treatment

Although conservative treatment for PD may resolve painful erections in most men, only a small percentage will experience a significant straightening of the penis. The aim of surgery is to correct curvature and allow penetrative intercourse. Surgery is indicated in patients with significant penile deformity and difficulty with intercourse associated with sexual bother. Patients must have a stable disease for three to six months (or more than nine to twelve months after onset of PD) [934, 943, 1025]. In addition to this requirement, there are other situations that may precipitate the indication for surgery, such as failed conservative or medical therapies, extensive penile plaque(s), or patient preference, when the disease is stable [1026, 1027].

Before considering reconstructive surgery, it is highly recommended to document the size and location of plaques, the degree of curvature, complex deformities (hinge, hourglass), the penile length and also the presence or absence of ED. The potential aims and risks of surgery should be discussed fully with the patient so that he can make an informed decision [1025]. Specific issues that should be mentioned during this discussion are the risks of penile shortening, ED, penile numbness and delayed orgasm, the risk of recurrent curvature, the potential for palpation of knots and stitches underneath the skin, and the potential need for circumcision at the time of surgery, including residual curvature and the risk of further penile wasting with shortening procedures [943, 1028]. Selection of the most appropriate surgical intervention is based on penile length assessment, curvature severity and erectile function status, including response to pharmacotherapy in cases of ED [943]. Patient expectations from surgery must also be included in the pre-operative assessment. The main objective of surgery is to achieve a "functionally straight" penis, and this must be fully understood by the patient to achieve the best possible satisfaction outcomes after surgery [1025, 1029].

Three major types of reconstruction may be considered for PD: i) tunical shortening procedures; ii) tunical lengthening procedures; and, iii) penile prosthesis implantation, with or without adjunct straightening techniques in the presence of concomitant ED and residual curvature [1030, 1031].

Tunical shortening procedures achieve straightening of the penis by shortening the longer, convex side of the penis to make it even with the contralateral side. Tunical lengthening procedures are performed on the concave side of the penis after making an incision or partial excision of the plaque, with coverage of the defect with a graft. Although tunical lengthening procedures in real life rarely lead to long-term penile length gain, they aim to minimise penile shortening caused by plication techniques of the tunica albuginea or correct complex deformities. In practice, tunical lengthening procedures are often combined with penile plication or shortening

procedures to correct the residual curvature [1032]. In patients with PD and ED not responding to medical treatments, penile prosthesis implantation can be considered with correction of the curvature including adjunct techniques (modeling, plication or incision/excision with grafting).

Penile degloving with associated circumcision (as a means of preventing post-operative phimosis) should be considered the standard approach for all types of procedures, although modifications have been described. Only one study has suggested that circumcision is not always necessary (e.g. in cases where the foreskin is normal pre-operatively) [1033]. Non-degloving techniques have been described that have been shown to prevent ischaemia and lymphatic complications after subcoronal circumcision [1034, 1035].

There are no standardised questionnaires for the evaluation of surgical outcomes. Data from well-designed prospective studies are scarce, with low levels of evidence. Data are mainly based on retrospective single-centre studies, typically non-comparative and non-randomised, or on expert opinion [943, 1036]. Therefore, surgical outcomes must be treated with caution.

8.2.3.2.1 Tunical shortening procedures

For men with good erectile function, adequate penile length, without complex deformities, such as an hourglass or hinge type narrowing abnormality, and non-severe curvature, a tunical shortening procedure can be considered an appropriate surgical approach. Numerous different techniques have been described, although they can be classified as excisional, incisional and plication techniques.

In 1965, Nesbit was the first to describe the removal of tunical ellipses opposite to the point of maximum curvature with a non-elastic corporal segment to treat CPC [1037]. Thereafter, this technique became a successful treatment option for PD-associated penile curvatures [1038]. This operation is based on a 5-10 mm transverse elliptical excision of the tunica albuginea or approximately 1 mm for each 10° of curvature. The overall short- and long-term results of the Nesbit operation are excellent [1039-1043]. Some modifications of the Nesbit procedure have been described (partial thickness shaving instead of conventional excision; underlapped U incision) with similar results, although these are in non-randomised studies [1044-1048].

The Yachia technique, on the other hand, is based on a completely different concept, as it utilises the Heinke-Mikowitz principle where a longitudinal tunical incision is closed transversely in order to shorten the convex side of the penis. This technique, initially described by Lemberger in 1984, was popularised by Yachia in 1990, when he reported a series of ten cases [1049-1054].

Pure plication techniques are simpler to perform. They are based on single or multiple plications performed without making excisions or incisions, in order to limit the potential damage to the veno-occlusive mechanism [945, 1055-1071]. Another modification has been described as the ’16-dot’ technique which consists of the application of two pairs of parallel Essed-Schroeder plications tensioned more or less depending on the degree of curvature [1048, 1072-1074]. The use of non-absorbable sutures or longer lasting abdsorbable sutures may reduce recurrence of the curvature (panel expert opinion). Results and satisfaction rates are both similar to the incision/excision procedures.

In general, using these tunical shortening techniques, complete penile straightening is achieved in more than 85% of patients. Recurrence of the curvature and penile hypoesthesia are uncommon (about 10%) and the risk of post-operative ED is low. Penile shortening is the most commonly reported outcome of these procedures. Shortening of 1-1.5 cm has been reported for about 22-69% of patients, which is rarely the cause of post-operative sexual dysfunction and patients may perceive the loss of length as greater than it actually is. It is therefore strongly advisable to measure and document the penile length peri-operatively, both before and after the straightening procedure, whatever the technique used (Table 30).

As mentioned above, there are multiple techniques with small modifications and all of them reported in retrospective studies, most of them without comparison between techniques and therefore the level of evidence is not sufficient to recommend one method over another.

Table 30: Results of tunical shortening procedures for PD data from different, non-comparable studies) [945, 1044-1071]

	Tunical shortening procedures				
	Nesbit	**Modified Nesbit**	**Yachia**	**16-dot / mod16-dot**	**Simple plication**
Number of patients / studies	652 / 4	387 / 5	150 / 6	285 / 5	1068 / 18
Significant penile shortening (%)*†	8.7% (5-39)	3.2% (0-13)	3.5% (0-10)	5.9% (0-6)	8.9% (0-55)

**Data are expressed as weighted average. † Defined as > 30 degrees of curvature. Ranges are in parentheses. ED = Erectile dysfunction.*

8.2.3.2.2 Tunical lengthening procedures

Tunical lengthening surgery is preferable in patients with significant penile shortening, severe curvature and/or complex deformities (hourglass, hinge) but without underlying ED. The definition of a severe curvature has been proposed to be greater than 60º, although there are no studies validating this threshold. However, it may be used as an informative guide to the patient and clinician in surgical counselling and planning, although there is no unanimous consensus based on the literature that such a threshold can predict surgical outcomes (panel expert consensus opinion). On the concave side of the penis, at the point of maximum curvature, which usually coincides with the location of the plaque, an incision is made, creating a defect in the albuginea that is covered with a graft. Complete plaque removal or plaque excision may be associated with higher rates of post-operative ED due to venous leak, but partial excision in cases of florid calcification may be permissible [1075, 1076]. Patients who do not have pre-operative ED should be informed of the significant risk of post-operative ED of up to 50% [1028].

Since 1974, when the first study using dermal grafting to treat PD was published [1077], a large number of different grafts have been used. The ideal graft should be resistant to traction, easy to suture and manipulate, flexible (not too much, to avoid aneurysmal dilations), readily available, morbidity should be minimal especially when using autografts and cost effective. No one graft material meets all of these requirements. Moreover, the studies performed do not compare different types of grafts and biomaterials and are often single-centre retrospective studies so there is not a single graft that can be recommended for surgeons [1078]. In addition, grafting procedures are associated with long term ED rates as high as 50%. The presence of pre-operative ED, the use of larger grafts, age more than 60 years, and ventral curvature are considered poor prognostic factors for good functional outcomes after grafting surgery [1031]. Although the risk for penile shortening appears to be less than that compared to the Nesbit, Yachia or plication procedures, it is still an issue and patients must be informed accordingly [1030]. Higher rates (3-52%) of penile hypoesthesia have also been described after these surgeries, as damage of the neurovascular bundle with dorsal curves (in the majority) is inevitable. A recent prospective study showed that 21% of patients had some degree of sensation loss at one week, 21% at one month, 8% at six months, and 3% at twelve months. [1029, 1079-1082]. The use of geometric principles introduced by Egydio may help to determine the exact site of the incision, and the shape and size of the defect to be grafted [1083].

Grafts for PD surgery can be classified into four types (Table 31) [935]:

- Autografts: taken from the individual himself, they include the dermis, vein, temporalis fascia, fascia lata, tunica vaginalis, tunica albuginea and buccal mucosa.
- Allografts: also of human origin but from a deceased donor, including the pericardium, fascia lata and dura mater.
- Xenografts: extracted from different animal species and tissues, including bovine pericardium, porcine small intestinal submucosa, bovine and porcine dermis, and TachoSil® (matrix of equine collagen).
- Synthetic grafts: these include Dacron® and Gore-Tex®.

All the autologous grafts have the inconvenience of possible graft harvesting complications. Dermal grafts are commonly associated with veno-occlusive ED (20%) due to lack of adaptability, so they have not been used in contemporary series [1077, 1078, 1084-1094]. Vein grafts have the theoretical advantage of endothelial-to-endothelial contact when grafted to underlying cavernosal tissue. The Saphenous vein has been the most common vein graft used [1095-1110]. For some extensive albuginea defects, more than one incision may be needed. Tunica albuginea grafts have obviously perfect histological properties but have some limitations: the size that can be harvested, and the risk of weakening penile support and making future procedures (penile prosthesis implantation) more complicated [1111-1113]. Tunica vaginalis is easy to harvest and has little tendency to contract due to its low metabolic requirements, although better results could be obtained if a vascular flap is used [1114-1118]. Under the pretext that by placing the submucosal layer on the corpus cavernosum the graft feeds on it and adheres more quickly, the buccal mucosal graft has recently been used with good short-term results [1119-1125].

Cadaveric dura mater is no longer used due to concerns about the possibility of infection [1081, 1126]. Cadaveric pericardium (Tutoplast©) offers good results by coupling excellent tensile strength and multidirectional elasticity/expansion by 30% [1029, 1076, 1090, 1127, 1128]. Cadaveric or autologous fascia lata or temporalis fascia offers biological stability and mechanical resistance [1129-1131].

Xenografts have become more popular in recent years. Small intestinal submucosa, a type I collagen-based xenogenic graft derived from the submucosal layer of the porcine small intestine, has been shown to promote tissue-specific regeneration and angiogenesis, and supports host cell migration, differentiation and the growth of endothelial cells, resulting in tissue structurally and functionally similar to the original [1132-1141]. As mentioned above, pericardium (bovine, in this case), has very good traction resistance and adaptability, and good host tolerance [1080, 1110, 1142-1144]. Grafting by collagen fleece (TachoSil©) in PD has some major advantages such as decreased operative times, easy application and an additional haemostatic effect [1079, 1145-1149].

It is generally recommended that synthetic grafts, including polyester (Dacron®) and polytetrafluoroethylene (Gore-Tex®) are avoided, due to increased risks of infection, secondary graft inflammation causing tissue fibrosis, graft contractures, and possibility of allergic reactions [1052, 1150-1153].

Some authors recommend post-operative penile rehabilitation to improve surgical outcomes. Some studies have described using VED and PTT to prevent penile length loss of up to 1.5 cm [1154]. In addition, daily nocturnal administration of PDE5I enhances nocturnal erections, encourages perfusion of the graft, and may minimise post-operative ED [1155]. Massages and stretching of the penis have also been recommended once wound healing is complete.

Table 31: Results of tunical lengthening procedures for Peyronie's disease (data from different, non- comparable studies) [1029, 1052, 1076, 1077, 1079-1081, 1084-1149]

	Year of publication	Number of patients / studies	Success (%)*	Penile shortening (%)*	De novo ED (%)*	Follow-up (mo)*
Autologous grafts						
Dermis	1974-2019	718 / 12	81.2% (60-100)	59.9% (40-75)	20.5% (7-67)	(6-180)
Vein grafts	1995-2019	690 / 17	85.6% (67-100)	32.7% (0-100)	14.8% (0-37)	(12-120)
Tunica albuginea	2000-2012	56 / 4	85.2% (75-90)	16.3% (13-18)	17.8% (0-24)	(6-41)
Tunica vaginalis	1980-2016	76 / 5	86.2% (66-100)	32.2% (0-83)	9.6% (0-41)	(12-60)
Temporalis fascia / Fascia lata	1991-2004	24 / 2	100%	0%	0%	(3-10)
Buccal mucosa	2005-2016	137 / 7	94.1% (88-100)	15.2% (0-80)	5.3% (0-10)	(12-45)
Allografts (cadaveric)						
Pericardium	2001-2011	190 / 5	93.1% (56-100)	23.1% (0-33)	37.8% (30-63)	(6-58)
Fascia lata	2006	14 / 1	78.6%	28.6%	7.1%	31
Dura matter	1988-2002	57 / 2	87.5%	30%	17.4% (15-23)	(42-66)
Xenografts						
Porcine SIS	2007-2018	429 / 10	83.9% (54-91)	19.6% (0-66)	21.9% (7-54)	(9-75)
Bovine pericardium	2002-2016	284 / 5	88.7% (81-100)	4.3% (0-41)	24.8% (0-50)	(14-67)
Bovine dermis	2016	28 / 1	93%	0%	25%	32
TachoSil®	2002-2018	477 / 6	93.1%	10.9% (0-93)	10.6% (0-21)	(0-63)

**Data are expressed as weighted average. Ranges are in parentheses.*
ED = Erectile dysfunction; SIS = Small intestinal submucosa.

The results of tunical shortening and lengthening approaches are presented in Tables 30 and 31. It must be emphasised that there are no RCTs available comparing surgical outcomes in PD. The risk of ED seems to be greater for penile lengthening procedures [943]. Recurrent curvature is likely to be the result of failure to wait until the disease has stabilised, re-activation of the condition following the development of stable disease, or the use of early re-absorbable sutures (e.g., Vicryl) that lose their strength before fibrosis has resulted in acceptable strength of the repair. Accordingly, it is recommended that only non-absorbable sutures or slowly re-absorbed absorbable sutures (e.g., PDS) should be used. Although with non-absorbable sutures, the knot should be buried to avoid troublesome irritation of the penile skin, but this issue may be alleviated by the use of slowly re-absorbable sutures (e.g., PDS) [1039]. Penile numbness is a potential risk of any surgical procedure, involving mobilisation of the dorsal neurovascular bundle. This will usually be a temporary neuropraxia, due to bruising of the dorsal sensory nerves. Given that the usual deformity is a dorsal deformity, the procedure most likely to induce this complication is a lengthening (grafting) procedure, or the association with although rare ventral curvatures [1030].

8.2.3.2.3 Penile prosthesis

Penile prosthesis (PP) implantation is typically reserved for the treatment of PD in patients with concomitant ED not responding to conventional medical therapy (PDE5I or intracavernosal injections of vasoactive agents) [943]. Although inflatable prostheses (IPP) have been considered classically more effective in the general population with ED, some studies support the use of malleable prostheses (MPP) in these patients with similar satisfaction rates [943, 1156, 1157]. The evidence suggests that there is no real difference between the available IPPs [1158]. Surgeons can and should advise on which type of prosthesis best suits the patient but it is the patient who should ultimately choose the prosthesis to be implanted [1159].

Most patients with mild-to-moderate curvature can expect an excellent outcome simply by cylinder insertion [1108, 1160]. If the curvature after placement of the prosthesis is < 30° no further action is indicated, since the prosthesis itself will act as an internal tissue expander to correct the curvature during the subsequent six to nine months. If, on the other hand, the curvature is > 30°, the first-line treatment would be modelling with the prosthesis maximally inflated (manually bent on the opposite side of the curvature for 90 seconds, often accompanied by an audible crack) [1161, 1162]. If, after performing this manoeuvre, a deviation > 30° persists, next steps would be eventually incision with collagen fleece coverage or without (if the defect is small, it can be left uncovered) or plaque incision and grafting [1163-1168]. However, the defect may be covered if it is larger, and this can be accomplished using grafts commonly employed in the grafting surgery (described above) which will prevent herniation and recurrent deformity due to the scarring of the defect [1169].

The risk of complications (infection, malformation, etc.) is not increased compared to the general population. However, a small risk of urethral perforation (3%) has been reported in patients with 'modeling' over the inflated prosthesis [1161].

In selected cases of end-stage PD with ED and significant penile shortening, a lengthening procedure, which involves simultaneous PP implantation and penile length restoration, such as the "sliding" technique has been considered [1170]. Although the "sliding" technique is not recommended due to reported cases of glans necrosis because of the concomitant release of both the neurovascular bundle and the urethra, new approaches for these patients have been recently described such as the MoST (Modified Sliding Technique), MUST (Multiple-Slit Technique) or MIT (Multiple-Incision Technique) techniques, but these should only be used in the hands of experienced high-volume surgeons and after full patient counseling [1171-1173].

While patient satisfaction after IPP placement in the general population is quite high, satisfaction rates have been found to be significantly lower in those with PD. Despite this, depression rates decreased after surgery in PD patients (from 19.3% to 10.9%) [1174]. The main cause of dissatisfaction after PPI in the general population is a shortened penile length. Therefore, patients with PD undergoing penile implant surgery must be counselled that they are not designed to restore their previous length [1174, 1175].

8.2.3.2.4 Summary of evidence for non-operative treatment of Peyronie's disease

Summary of evidence	**LE**
Surgery for PD should only be offered in patients with stable disease with functional impairment.	2b
In patients with concomitant PD and ED without response to medical treatment, penile prosthesis implantation with or without additional straightening manouevres is the technique of choice.	2a
In other cases, factors such as penile length, rigidity of the erections, degree of curvature, presence of complex deformities and patient choice must be taken into account in order to decide on a tunical shortening or lengthening technique.	3

8.2.3.2.5 Recommendations for the surgical treatment of penile curvature

Recommendations	Strength rating
Perform surgery only when Peyronie's disease (PD) has been stable for at least three months (without pain or deformity deterioration), which is usually the case after twelve months from the onset of symptoms, and intercourse is compromised due to deformity.	Strong
Prior to surgery, assess penile length, curvature severity, erectile function (including response to pharmacotherapy in case of erectile dysfunction [ED]) and patient expectations.	Strong
Use tunical shortening procedures as the first treatment option for congenital penile curvature and for PD with adequate penile length and rigidity, non-severe curvature and absence of complex deformities (hour-glass, hinge). The type of procedure used is dependent on surgeon and patient preference, as no procedure has proven superior to its counterparts.	Weak
Use tunical lengthening procedures for patients with PD and normal erectile function, without adequate penile length, severe curvature or presence of complex deformities (hour-glass, hinge). The type of graft used is dependent on the surgeon and patient factors, as no graft has proven superior to its counterparts.	Weak
Use the sliding techniques with caution, as there is a significant risk of life changing complications (e.g., glans necrosis).	Strong
Do not use synthetic grafts in PD reconstructive surgery.	Strong
Use penile prosthesis implantation, with or without any additional procedure (modeling, plication, incision or excision with or without grafting), in PD patients with ED not responding to pharmacotherapy.	Strong

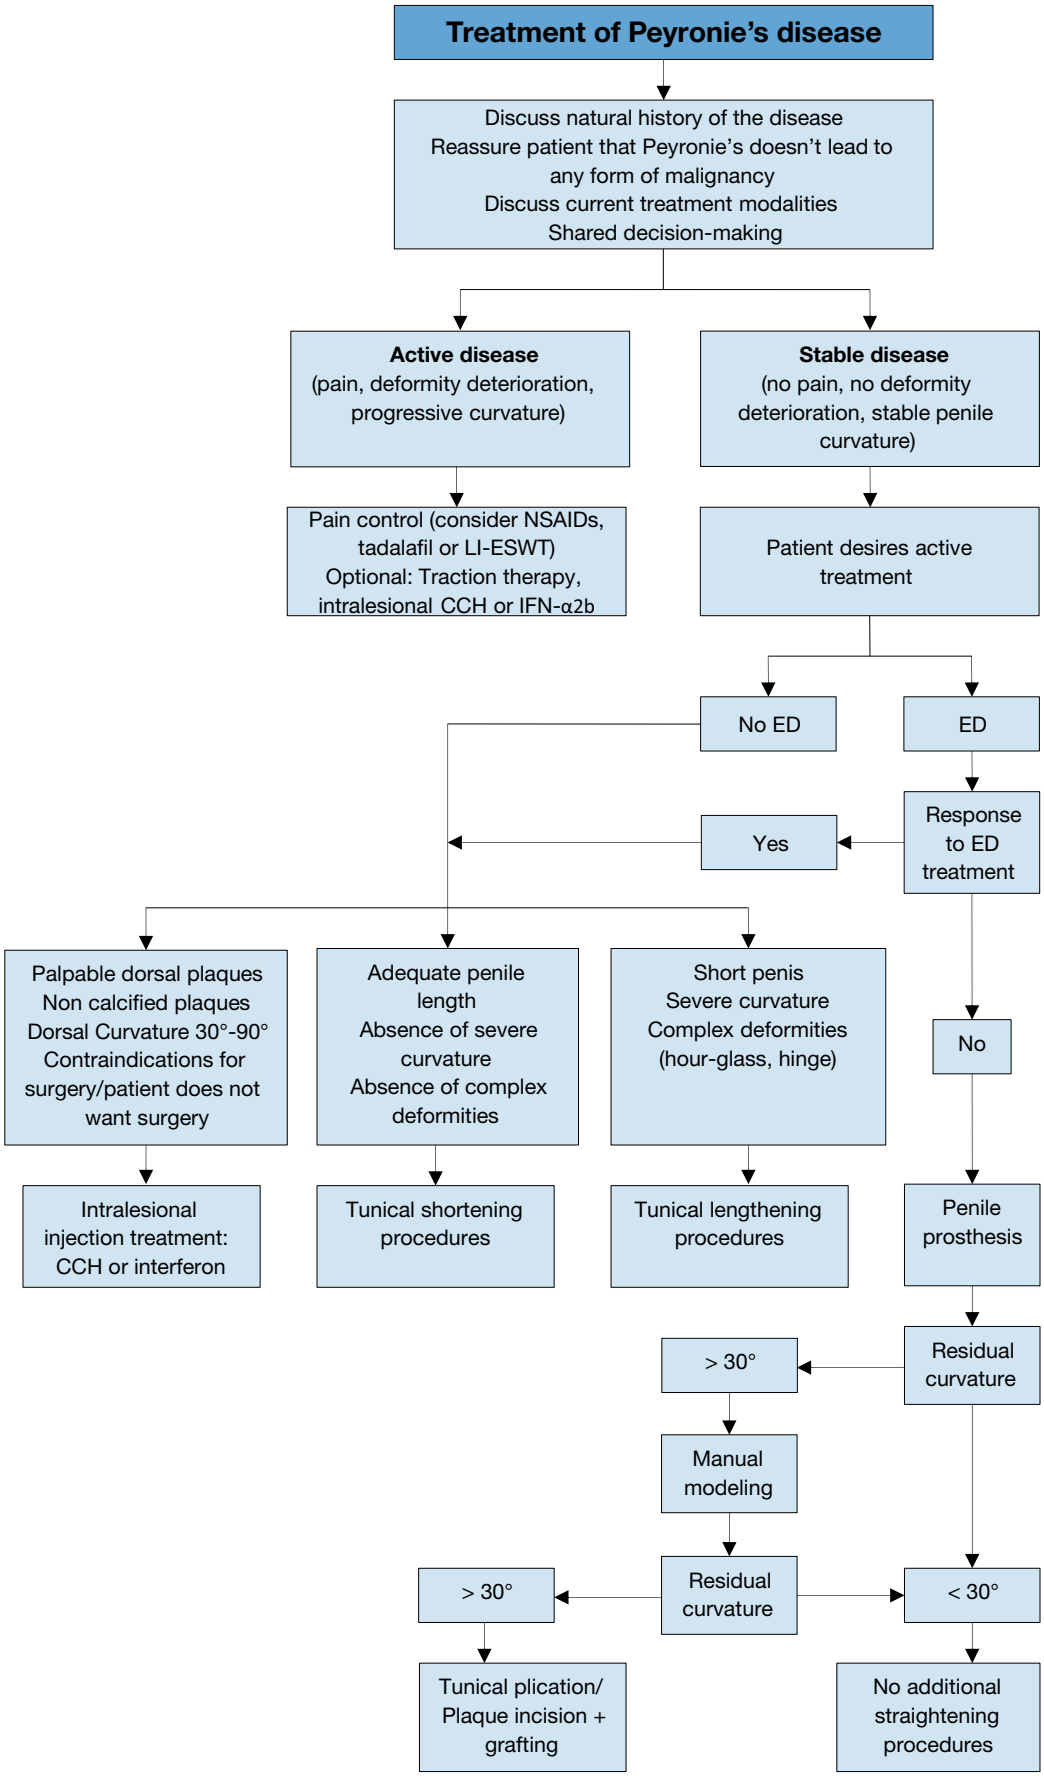
8.2.3.3 Treatment algorithm

As mentioned above, in the active phase of the disease, most therapies are experimental or with low evidence. In cases of pain, LI-ESWT, tadalafil and NSAIDs can be offered. In cases of curvature or shortening, traction therapy has demonstrated good responses.

When the disease has stabilised, intralesional treatments (mainly CCH) or surgery may be used. Intralesional treatments may reduce the indication of the surgery or change the technique to be performed but only after full patient counselling which should also include a cost benefit discussion with the patient.

The decision on the most appropriate surgical procedure to correct penile curvature is based on pre-operative assessment of penile length, the degree of the curvature and erectile function status. In non-complex and non-severe deformities, tunical shortening procedures are acceptable and are usually the method of choice. This is typically the case for PC. If a severe curvature or a complex deformation is present (hourglass, or hinge), or if the penis is significantly shortened in patients with a good erectile function (preferably without pharmacological treatment), then a tunical lengthening procedure is feasible, using any of the grafts previously mentioned. If there is concomitant ED, which is not responsive to pharmacological treatment, the best option is the implantation of a penile prosthesis, with or without a straightening procedure over the penis (modeling, plication, incision or excision with or without grafting). The treatment algorithm is presented in Figure 11.

Figure 11: Treatment algorithm for Peyronie's disease



ED = erectile dysfunction; LI-ESWT= Low-intensity Extracorporeal shockwave treatment.

9. MALE INFERTILITY

9.1 Definition and classification

Infertility is the inability of a sexually active, non-contraceptive couple to achieve spontaneous pregnancy in one year [1176]. Primary infertility refers to couples that have never had a child and cannot achieve pregnancy after at least twelve consecutive months having sex without using birth control methods. Secondary infertility refers to infertile couples who have been able to achieve pregnancy at least once before.

9.2 Epidemiology/aetiology/pathophysiology/risk factors

9.2.1 Introduction

About 15% of couples do not achieve pregnancy within one year and seek medical treatment for infertility. One in eight couples encounter problems when attempting to conceive a first child and one in six when attempting to conceive a subsequent child. Three percent of women who are currently trying to conceive remain involuntarily childless, while 6% of parous women are not able to have as many children as they would wish [1177]. In 50% of involuntarily childless couples, a male-infertility-associated factor is found, usually together with abnormal semen parameters [1176]. For this reason, all male patients belonging to infertile couples should undergo medical evaluation by an urologist trained in male reproduction.

Male fertility can be impaired as a result of [1176]:

- congenital or acquired urogenital abnormalities;
- malignancies;
- urogenital tract infections;
- increased scrotal temperature (e.g., as a consequence of varicocele);
- endocrine disturbances;
- genetic abnormalities;
- immunological factors.

In 30-40% of cases, no male-associated factor is found to explain impairment of sperm parameters and historically was referred to as idiopathic male infertility. These men present with no previous history of diseases affecting fertility and have normal findings on physical examination and endocrine, genetic and biochemical laboratory testing, although semen analysis may reveal pathological findings (see 9.3.2). On the other hand, unexplained male infertility is defined as infertility of unknown origin with normal sperm parameters. It is now believed that idiopathic male infertility may be associated with several previously unidentified pathological factors, which include but are not limited to endocrine disruption as a result of environmental pollution, generation of reactive oxygen species/sperm DNA damage, or genetic and epigenetic abnormalities [1178].

Advanced paternal age has emerged as one of the main risk factors associated with the progressive increase in the prevalence of male factor infertility [1179-1182]. Table 32 summarises the main male-infertility-associated factors.

Table 32: Male infertility causes and associated factors and percentage of distribution in 10,469 patients [1183]

Diagnosis	Unselected patients (n = 12,945)	Azoospermic patients (n = 1,446)
All	100%	11.2%
Infertility of known (possible) cause	42.6%	42.6%
Maldescended testes	8.4	17.2
Varicocele	14.8	10.9
Sperm auto-antibodies	3.9	-
Testicular tumour	1.2	2.8
Others	5.0	1.2
Idiopathic infertility	30.0	13.3
Hypogonadism	10.1	16.4
Klinefelter syndrome (47, XXY)	2.6	13.7
XX male	0.1	0.6
Primary hypogonadism of unknown cause	2.3	0.8
Secondary (hypogonadotropic) hypogonadism	1.6	1.9
Kallmann syndrome	0.3	0.5

Idiopathic hypogonadotropic hypogonadism	0.4	0.4
Residual after pituitary surgery	< 0.1	0.3
Late-onset hypogonadism	2.2	-
Constitutional delay of puberty	1.4	-
Others	0.8	0.8
General/systemic disease	2.2	0.5
Cryopreservation due to malignant disease	7.8	12.5
Testicular tumour	5.0	4.3
Lymphoma	1.5	4.6
Leukaemia	0.7	2.2
Sarcoma	0.6	0.9
Disturbance of erection/ejaculation	2.4	-
Obstruction	2.2	10.3
Vasectomy	0.9	5.3
Cystic fibrosis (CBAVD)	0.5	3.0
Others	0.8	1.9

CBAVD = Congenital bilateral absence of the vas deferens.

*9.2.2 **Recommendations on epidemiology and aetiology***

Recommendations	Strength rating
Investigate both partners simultaneously to categorise the cause of infertility.	Strong
Examine all men seeking medical help for fertility problems, including men with abnormal semen parameters for urogenital abnormalities.	Strong

9.3 Diagnostic work-up

A focused evaluation of the male patient must always be undertaken and should include: a medical and reproductive history; physical examination; semen analysis - with strict adherence to World Health Organization (WHO) reference values for human semen characteristics [1184], and hormonal evaluation. Other investigations (e.g., genetic analysis and imaging) may be required depending on the clinical features and semen parameters.

*9.3.1 **Medical/reproductive history and physical examination***

9.3.1.1 Medical and reproductive history

Medical history should evaluate any risk factors and behavioural patterns which could affect the male partner's fertility, such as lifestyle, family history (including, testis cancer), comorbid conditions (including, systemic diseases; e.g., hypertension; diabetes mellitus; obesity; MetS; testis cancer, etc.), genito-urinary infections (including, sexually transmitted infections), past history of surgery of the testis and excluding any potential known gonadotoxins.

Typical findings from the history of a patient with infertility include:

- cryptorchidism (uni- or bilateral);
- testicular torsion and trauma;
- genitourinary infections;
- exposure to environmental toxins;
- gonadotoxic medications (anabolic drugs, chemotherapeutic agents, etc.);
- exposure to radiation or cytotoxic agents.

9.3.1.2 Physical examination

A focused physical examination is compulsory in the evaluation of every infertile male, including presence of secondary sexual characteristics. The size, texture and consistency of the testes must be evaluated. In clinical practice, testis volume is assessed by Prader's orchidometer [1185]; orchidometry may over-estimate testis volume when compared with US assessment [1186]. There are no uniform reference values in terms of Prader's orchidometer-derived testis volume, due to differences in the populations studied (e.g., geographic area, nourishment, ethnicity and environmental factors) [1185-1187]. The mean Prader's orchidometer-derived testis volume reported in the European general population is 20.0±5.0 mL [1185], whereas in infertile patients it is 18.0±5.0 mL [1185, 1188, 1189]. The presence of the vas deferens, fullness of epididymis and presence of a varicocele should be always determined. Likewise, palpable abnormalities of the testis, the epididymis, and the vas deferens should be evaluated. Other physical alterations, such as abnormalities of the penis (e.g.,

phimosis, short frenulum, fibrotic nodules, epispadias, hypospadias, etc.), abnormal body hair distribution and gynecomastia, should also be evaluated.

Typical findings from the physical examination of a patient with characteristics suggestive for testicular deficiency include:

- abnormal secondary sexual characteristics;
- abnormal testicular volume and/or consistency;
- testicular masses (potentially suggestive of cancer);
- absence of testes (uni-bilaterally);
- gynaecomastia;
- varicocele.

*9.3.2 **Semen analysis***

A comprehensive andrological examination is always indicated if semen analysis shows abnormalities as compared with reference values (Table 33). Important treatment decisions are based on the results of semen analysis; therefore, it is essential that the complete laboratory work-up is standardised. Ejaculate analysis has been standardised by the WHO and disseminated by publication of the most updated version of the WHO Laboratory Manual for the Examination and Processing of Human Semen (5th edn.) [1190]. There is consensus that modern semen analysis must follow these guidelines. However it has also become clear from studies that more complex testing than semen analysis may be required, particularly in men belonging to couples with recurrent pregnancy loss from natural conception or assisted reproductive technologies (ART) and men with unexplained male infertility. In these patients there is evidence that the sperm DNA may be damaged, thus resulting in pregnancy failure [1178] (see below).

Table 33: Lower reference limits (5th centiles and their 95% CIs) for semen characteristics

Parameter	**Lower reference limit (range)**
Semen volume (mL)	1.5 (1.4-1.7)
Total sperm number (10^6/ejaculate)	39 (33-46)
Sperm concentration (10^6/mL)	15 (12-16)
Total motility (PR + NP)	40 (38-42)
Progressive motility (PR, %)	32 (31-34)
Vitality (live spermatozoa, %)	58 (55-63)
Sperm morphology (normal forms, %)	4 (3.0-4.0)
Other consensus threshold values	
pH	> 7.2
Peroxidase-positive leukocytes (10^6/mL)	< 1.0
Optional investigations	
MAR test (motile spermatozoa with bound particles, %)	< 50
Immunobead test (motile spermatozoa with bound beads, %)	< 50
Seminal zinc (µmol/ejaculate)	≥ 2.4
Seminal fructose (µmol/ejaculate)	≥ 13
Seminal neutral glucosidase (mU/ejaculate)	≤ 20

CIs = confidence intervals; MAR = mixed antiglobulin reaction; NP = non-progressive; PR = progressive (a+b motility).

If the results of semen analysis are normal according to WHO criteria, a single test is sufficient. If the results are abnormal on at least two tests, further andrological investigation is indicated. It is important to differentiate between the following:

- oligozoospermia: < 15 million spermatozoa/mL;
- asthenozoospermia: < 32% progressive motile spermatozoa;
- teratozoospermia: < 4% normal forms.

Often, all three anomalies occur simultaneously, which is defined as oligo-astheno-teratozoospermia (OAT) syndrome. As in azoospermia (namely, the complete absence of spermatozoa in semen), in severe cases of oligozoospermia (spermatozoa < 5 million/mL) [1191], there is an increased incidence of obstruction of the male genital tract and genetic abnormalities. In those cases, a more comprehensive assessment of the hormonal profile may be helpful to further and more accurately differentially diagnose among pathologic conditions.

In azoospermia, the semen analysis may present with normal ejaculate volume and azoospermia after centrifugation. A recommended method is semen centrifugation at 3,000 g for fifteen minutes and a thorough microscopic examination by phase contrast optics at ×200 magnification of the pellet. All samples can be stained and re-examined microscopically [1190]. This is to ensure that small quantities of sperm are detected, which may be potentially used for intracytoplasmic sperm injection (ICSI) and obviate the need to surgical intervention.

*9.3.3 **Measurement of sperm DNA Fragmentation Index (DFI)***

Semen analysis is a descriptive evaluation, and may be unable to discriminate between the sperm of fertile and infertile men. Therefore, it is now apparent that sperm DNA damage may occur in men with infertility. DNA fragmentation, or the accumulation of single- and double-strand DNA breaks, is a common property of sperm, and an increase in the level of sperm DNA fragmentation has been shown to reduce the chances of natural conception. In this context, sperm DNA damage is more common in infertile men and sperm DNA damage has been identified as a major contributor to male infertility, as well as poorer outcomes following ART [1192, 1193], including impaired embryo development [1192], miscarriage, recurrent pregnancy loss [1192, 1194], and birth defects in the offspring [1192]. Sperm DNA damage can be increased by a number of factors including hormonal anomalies, varicocele, chronic infection and lifestyle factors (e.g., smoking) [1193].

A number of assays have been described to measure sperm DNA damage. It has been suggested that current methods for assessing sperm DNA integrity still do not reliably predict treatment outcomes from ART and controversy exists as whether to recommend them routinely for clinical use [1193, 1195]. Of those, terminal deoxynucleotidyl transferase mediated deoxyuridine triphosphate nick end labeling (TUNEL) and the alkaline comet test (COMET), are tests that directly measure DNA damage. Conversely, sperm chromatin structure assay (SCSA) and sperm chromatic dispersion test (SCD) are indirect tools for DNA fragmentation assessment. Sperm chromatin structure assay is still the most widely studied and one of the most commonly used techniques to detect DNA damage [1196, 1197]. In SCSA, the number of cells with DNA damage is indicated by the DNA fragmentation index (DFI,%) [1198], whereas the proportion of immature sperm with defects in the histone-to-protamine transition is indicated by high DNA stainability [1199]. It is suggested that a threshold value of DFI of 30% as measured with SCSA, is associated with reduced pregnancy rates via natural conception or Intra-uterine insemination (IUI) [1197]. Furthermore, DFI values of over 50% on SCSA have been associated with poorer outcomes from *in vitro* fertilisation (IVF) treatment. More recently, the mean COMET score and scores for proportions of sperm with high or low DNA damage have been shown to be of value in diagnosing male infertility and providing additional discriminatory information for the prediction of both IVF and ICSI live births [1193].

Testicular sperm has been reported to have lower levels of sperm DFI when compared to ejaculated sperm [1200]. Couples with elevated DNA fragmentation may benefit from the combination of testicular sperm extraction (TESE) and ICSI, an approach called TESE-ICSI, which may not overcome infertility when applied to an unselected population of infertile men with untested DNA fragmentation values [1197, 1200]. However, further evidence is needed to support this practice in the routine clinical setting [1200].

*9.3.4 **Hormonal determinations***

In men with testicular deficiency, hypergonadotropic hypogonadism (also called primary hypogonadism) is usually present, with high levels of FSH and LH, with or without low levels of testosterone. Generally, the levels of FSH negatively correlate with the number of spermatogonia [1201]. When spermatogonia are absent or markedly diminished, FSH values are usually elevated; when the number of spermatogonia is normal, but maturation arrest exists at the spermatocyte or spermatid level, FSH values are usually within the normal range [1201]. However, for patients undergoing TESE, FSH levels do not accurately predict the presence of spermatogenesis, as men with maturation arrest on histology can have both normal FSH and testis volume [1202, 1203]. Furthermore men with non-obstructive azoospermia (NOA) and high levels of FSH may still harbour focal areas of spermatogenesis at the time of TESE or microdissection TESE (mTESE) [1203].

*9.3.5 **Genetic testing***

All urologists working in andrology must have an understanding of the genetic abnormalities most commonly associated with infertility, so that they can provide correct advice to couples seeking fertility treatment. Men with very low sperm counts can still be offered a reasonable chance of paternity, using IVF, ICSI and sperm extraction from the testes in cases of azoospermia. However, the spermatozoa of infertile men shows an increased rate of aneuploidy, structural chromosomal abnormalities, and DNA damage, carrying the risk of passing genetic abnormalities to the next generation. Current routine clinical practice is based on the screening of genomic DNA from peripheral blood samples. However, screening of chromosomal anomalies

in spermatozoa (sperm aneuploidy) is also feasible and can be performed in selected cases (e.g., recurrent miscarriage) [1204-1206].

9.3.5.1 Chromosomal abnormalities

Chromosome abnormalities can be numerical (e.g. trisomy) or structural (e.g. inversions or translocations). In a survey of pooled data from eleven publications, including 9,766 infertile men, the incidence of chromosomal abnormalities was 5.8% [1207]. Of these, sex chromosome abnormalities accounted for 4.2% and autosomal abnormalities for 1.5%. In comparison, the incidence of abnormalities was 0.38% in pooled data from three series, with a total of 94,465 newborn male infants, of which 131 (0.14%) were sex chromosome abnormalities and 232 (0.25%) autosomal abnormalities [1207]. The frequency of chromosomal abnormalities increases as testicular deficiency becomes more severe. Patients with sperm count < 5 million/mL already show a ten-fold higher incidence (4%) of mainly autosomal structural abnormalities compared with the general population [1208, 1209]. Men with NOA are at highest risk, especially for sex chromosomal anomalies (e.g., Klinefelter Syndrome) [1210, 1211].

Based on the frequencies of chromosomal aberrations in patients with different sperm concentration, karyotype analysis is currently indicated in men with azoospermia or oligozoospermia (spermatozoa < 10 million/mL) [1209]. This broad selection criterion has been recently externally validated, with the finding that the suggested threshold has a relatively low sensitivity, specificity, and discrimination (namely, 80%, 37%, and 59%, respectively) [1212]. In this context, a novel nomogram, with a 2% probability cut-off, which allows for a more careful detection of karyotype alterations has been developed [1212]. Notwithstanding, the clinical value of spermatozoa < 10 million/mL remains a valid threshold until further studies, evaluating the cost-effectiveness, in which costs of adverse events due to chromosomal abnormalities (e.g. miscarriages and children with congenital anomalies) are performed [1213]. If there is a family history of recurrent spontaneous abortions, malformations or mental retardation, karyotype analysis should be requested, regardless of the sperm concentration.

9.3.5.1.1 Sex chromosome abnormalities (Klinefelter syndrome and variants [47,XXY; 46,XY/47, XXY mosaicism])

Klinefelter Syndrome is the most common sex chromosome abnormality [1214]. Adult men with Klinefelter Syndrome usually have small firm testicles along with features of primary hypogonadism. The phenotype is the final result of a combination between genetic, hormonal and age-related factors [15]. As a whole, the phenotype varies from that of a normally virilised male to one with the stigmata of androgen deficiency. In the vast majority of the cases infertility and reduced testis volume are the only clinical features that can be detected. Leydig cell function is also commonly impaired in men with Klinefelter Syndrome and thus testosterone deficiency is more frequently observed than that in the general population, although rarely observed during the peri-pubertal period, which usually occurs in a normal manner [15, 1215]. Rarely, more pronounced signs and symptoms of hypogonadism can be present, along with congenital abnormalities including heart and renal problems [1216].

The presence of germ cells and sperm production are variable in men with Klinefelter Syndrome and are more frequently observed in mosaicism, 46,XY/47,XXY. Based on sperm fluorescence *in situ* hybridisation (FISH) studies showing an increased frequency of sex chromosomal abnormalities and increased incidence of autosomal aneuploidy (disomy for chromosomes 13, 18 and 21), concerns have been raised about the chromosomal normality of the embryos generated through ICSI [1217]. The production of 24,XY sperm has been reported in 0.9% and 7.0% of men with Klinefelter's mosaicism [1218, 1219] and in 1.36-25% of men with somatic karyotype 47,XXY [1220-1223]. In patients with azoospermia, TESE or mTESE are therapeutic options as spermatozoa can be recovered in up to 50% of cases [1224] [1225]. There is growing evidence that TESE or mTESE yields higher sperm recovery rates when performed at a younger age [1210, 1226].

Numerous healthy children have been born using ICSI without pre-implantation genetic diagnosis (PGD) although the conception of one 47,XXY foetus has been reported [1214]. Although data published so far have not reported any difference in the prevalence of aneuploidies in children conceived using ICSI in Klinefelter Syndrome compared to the general population, men with Klinefelter Syndrome undergoing fertility treatments should be counselled regarding the potential genetic abnormalities in their offspring.

Regular medical follow-up of men with Klinefelter Syndrome is recommended as androgen replacement therapy may be considered if testosterone levels are in the hypogonadal range when fertility issues have been addressed. Since this syndrome is associated with a number of general health problems, appropriate medical follow-up is therefore advised [16, 1227, 1228]. In particular, men with Klinefelter Syndrome are at higher risk

of metabolic and carviovascular diseases (CVD), including venous thromoembolism (VTE). Therefore, men with Klinefelter Syndrome should be made aware of this risk, particularly when starting testosterone treatment TRT [1229]. In addition, a higher risk of haemathological malignances has been reported in men with Klinefelter Syndrome [16].

Testicular sperm extraction in peri-pubertal or pre-pubertal Klinefelter boys aiming at cryopreservation of testicular spermatogonial stem cells is to be still considered experimental and should only be performed within a research setting [1230]. The same applies to sperm retrieval in older boys who have not considered their fertility potential [1231].

9.3.5.1.2 Autosomal abnormalities

Genetic counselling should be offered to all couples seeking fertility treatment (including IVF/ICSI) when the male partner has an autosomal karyotype abnormality. The most common autosomal karyotype abnormalities are Robertsonian translocations, reciprocal translocations, paracentric inversions, and marker chromosomes. It is important to look for these structural chromosomal anomalies because there is an increased associated risk of aneuploidy or unbalanced chromosomal complements in the foetus. As with Klinefelter Syndrome, sperm FISH analysis provides a more accurate risk estimation of affected offspring. However, the use of this genetic test is largely limited by the availability of laboratories able to perform this analysis [1232]. When IVF/ICSI is carried out for men with translocations, PGD or amniocentesis should be performed [1233, 1234].

9.3.5.2 Cystic fibrosis gene mutations

Cystic fibrosis (CF) is an autosomal-recessive disorder [1235]. It is the most common genetic disease of Caucasians; 4% are carriers of gene mutations involving the CF transmembrane conductance regulator (CFTR) gene located on chromosome 7p. It encodes a membrane protein that functions as an ion channel and influences the formation of the ejaculatory duct, seminal vesicle, vas deferens and distal two-thirds of the epididymis. Congenital bilateral absence of the vas deferens (CBAVD) is associated with CFTR gene mutations and was also found in ~2% of men with obstructive azoospermia [1236]. Clinical diagnosis of absent vasa is easy to miss and all men with azoospermia should be very carefully examined to exclude CBAVD, particularly those with a semen volume < 1.0 mL and acidic pH < 7.0 [1237-1239]. Approximately 1,500 mutations are listed on the CFTR database http://www.genetsickkids.on.ca/cftr/.

The most frequently found mutations are the F508, R117H and W1282X, but their frequency and the presence of other mutations largely depend on the ethnicity of the patient [1240, 1241]. Given the functional relevance of a DNA variant (the 5T allele) in a non-coding region of CFTR [1242], it is now considered a mild CFTR mutation rather than a polymorphism and it should be analysed in each CBAVD patient. As more mutations are defined and tested for, almost all men with CBAVD will probably be found to have mutations. It is not practical to test for all known mutations, because many have a very low prevalence in a particular population. Routine testing is usually restricted to the most common mutations in a particular community through the analysis of a mutation panel. Men with CBAVD often have mild clinical stigmata of CF (e.g., history of chest infections). When a man has CBAVD, it is important to test also his partner for CF mutations. If the female partner is found to be a carrier of CFTR mutations, the couple must consider very carefully whether to proceed with ICSI using the male's sperm, as the risk of having a child with CF or CBAVD will be 50%, depending on the type of mutations carried by the parents. If the female partner is negative for known mutations, the risk of being a carrier of unknown mutations is ~0.4% [1243].

9.3.5.2.1 Unilateral or bilateral absence/abnormality of the vas and renal anomalies

Unilateral absence of the vas deferens is usually associated with ipsilateral absence of the kidney and probably has a different genetic causation [1244]. Consequently, in these subjects CFTR mutation screening is not indicated. Men with unilateral absence of the vas deferens are usually fertile, and the condition is most commonly encountered as an incidental finding in the vasectomy clinic. Cystic fibrosis transmembrane conductance regulator gene mutation screening is indicated in men with unilateral absence of the vas deferens with normal kidneys. The prevalence of renal anomalies is extremely rare for patients who have CBAVD and CFTR mutations [1245]. An abdominal US should be undertaken both in unilateral and bilateral absence of vas deferens without CTFR mutations. Findings may range from unilateral absence of the vas deferens with ipsilateral absence of the kidney, to bilateral vessel and renal abnormalities, such as pelvic kidney [1246].

9.3.5.3 Y microdeletions - partial and complete

Microdeletions on the Y-chromosome are termed AZFa, AZFb and AZFc deletions [1247]. Clinically relevant deletions remove partially, or in most cases completely, one or more of the AZF regions, and are the most frequent molecular genetic cause of severe oligozoospermia and azoospermia [1248]. In each AZF region,

there are several spermatogenesis candidate genes [1249]. Deletions occur *en bloc* (i.e. removing more than one gene), it is not possible to determine the role of a single AZF gene from the AZF deletion phenotype and it is unclear if they all participate in spermatogenesis. Gene-specific deletions, which remove a single gene, have been reported only in the AZFa region and concern the USP9Y gene. These studies have suggested that USP9Y is most likely to be a "fine tuner" of sperm production, and its specific screening is not advised [1250].

9.3.5.3.1 Clinical implications of Y microdeletions

The clinical significance of Yq microdeletions can be summarised as follows:

- They are not found in normozoospermic men, proving there is a clear cut cause-and-effect relationship between Y-deletions and spermatogenic failure [1251].
- The highest frequency of Y-deletions is found in azoospermic men (8-12%), followed by oligozoospermic (3-7%) men [1252, 1253].
- Deletions are extremely rare with a sperm concentration > 5 million/mL (~0.7%).
- AZFc deletions are most common (65-70%), followed by Y-deletions of the AZFb and AZFb+c or AZFa+b+c regions (25-30%). AZFa region deletions are rare (5%) [1254].
- Complete deletion of the AZFa region is associated with severe testicular phenotype (Sertoli cell only syndrome), while complete deletions of the AZFb region is associated with spermatogenic arrest. Complete deletions that include the AZFa and AZFb regions are of poor prognostic significance for retrieving sperm at the time of TESE and sperm is not found in these patients. Therefore, TESE should not be attempted in these patients [1255, 1256].
- Deletions of the AZFc region causes a variable phenotype ranging from azoospermia to oligozoospermia.
- Sperm can be found in up to 50%-75%of men with AZFc microdeletions [1255-1257].
- Men with AZFc microdeletions who are oligozoospermic or in whom sperm is found at the time of TESE must be counselled that any male offspring will inherit the deletion.
- Classical (complete) AZF deletions do not confer a risk for cryptorchidism or testicular cancer [1258, 1259].

The specificity and genotype/phenotype correlation reported above means that Y-deletion analysis has both a diagnostic and prognostic value for testicular sperm retrieval [1258].

9.3.5.3.1.1 Testing for Y microdeletions

Historically, indications for AZF deletion screening are based on sperm count and include azoospermia and severe oligozoospermia (spermatozoa count < 5 million/mL). A recent single meta-analysis assessing the prevalence of microdeletions on the Y chromosome in oligozoospermic men in thirty-seven European and North American studies (n = 12,492 oligozoospermic men) showed that the majority of microdeletions occur in men with sperm concentrations of ≤ 1 million sperm/mL, with < 1% identified in men with > 1 million sperm/mL [1259]. In this context, whilst an absolute threshold for clinical testing cannot be universally given, patients may be offered testing if sperm counts are less than 5 million sperm/mL, but should be necessarily tested if less than ≤1 million sperm/mL.

With the efforts of the European Academy of Andrology (EAA) guidelines and the European Molecular Genetics Quality Network external quality control program (http://www.emqn.org/emqn/), Yq testing has become more reliable in different routine genetic laboratories. The EAA guidelines provide a set of primers capable of detecting > 95% of clinically relevant deletions [1260].

9.3.5.3.1.2 Genetic counselling for AZF deletions

After conception, any Y-deletions are transmitted to the male offspring, and genetic counselling is therefore mandatory. In most cases, father and son will have the same microdeletion [1260], but occasionally the son may have a more extensive deletion [1261]. The extent of spermatogenic failure (still in the range of azoo-/oligozoospermia) cannot be predicted entirely in the son, due to the different genetic background and the presence or absence of environmental factors with potential toxicity on reproductive function. A significant proportion of spermatozoa from men with complete AZFc deletion are nullisomic for sex chromosomes [1262, 1263], indicating a potential risk for any offspring to develop 45,X0 Turner's syndrome and other phenotypic anomalies associated with sex chromosome mosaicism, including ambiguous genitalia [1264]. Despite this theoretical risk, babies born from fathers affected by Yq microdeletions are phenotypically normal [1258, 1260]. This could be due to the reduced implantation rate and a likely higher risk of spontaneous abortion of embryos bearing a 45,X0 karyotype.

9.3.5.3.1.3 Y-chromosome: 'gr/gr' deletion

A new type of Yq deletion, known as the gr/gr deletion, has been described in the AZFc region [1265]. This deletion removes half of the gene content of the AZFc region, affecting the dosage of multicopy genes mapping inside this region. This type of deletion confers a 2.5-8 fold increased risk for oligozoospermia [1260, 1266-1268]. The frequency of gr/gr deletion in oligozoospermic patients is ~5% [1269].

According to four meta-analyses, gr/gr deletion is a significant risk factor for impaired sperm production [1267-1269]. It is worth noting that both the frequency of gr/gr deletion and its phenotypic expression vary between different ethnic groups, depending on the Y-chromosome background. For example, in some Y haplo-groups, the deletion is fixed and appears to have no negative effect on spermatogenesis. Consequently, the routine screening for gr/gr deletion is still a debated issue, especially in those laboratories serving diverse ethnic and geographic populations. A large multicenter study has shown that gr/gr deletion is a potential risk factor for testicular germ cell tumours [1242]. However, these data need further confirmation in an ethnically and geographically matched case-control study setting. For genetic counselling it is worth noting that partial AZFc deletions, gr/gr and b2/b3, may predispose to complete AZFc deletion in the next generation [1270].

9.3.5.3.1.4 Autosomal defects with severe phenotypic abnormalities and infertility

Several inherited disorders are associated with severe or considerable generalised abnormalities and infertility (e.g., Prader-Willi Syndrome [1271], Bardet-Biedl Syndrome [1272], Noonan's Syndrome, Myotonic dystrophy, dominant polycystic kidney disease [1273, 1274], 5 α-reductase deficiency [1275-1278], etc). Pre-implantation genetic screening (PGS) may be necessary in order to improve the ART outcomes among men with autosomal chromosomal defects [1279, 1280].

9.3.5.4 Sperm chromosomal abnormalities

Sperm can be examined for their chromosomal constitution using FISH both in men with normal karyotype and with anomalies. Aneuploidy in sperm, particularly sex chromosome aneuploidy, is associated with severe damage to spermatogenesis [1207, 1281-1283] and with translocations and may lead to recurrent pregnancy loss (RPL) or recurrent implantation failure [1284]. In a large retrospective series, couples with normal sperm FISH had similar outcomes from IVF and ICSI on PGS. However, couples with abnormal FISH had better clinical outcomes after PGS, suggesting a potential contribution of sperm to aneuploidic abnormalities in the embryo [1285]. In men with sperm aneuploidy, PGS combined with IVF and ICSI can increase chances of live births [1206].

9.3.5.5 Measurement of Oxidative Stress

Oxidative Stress (OS) is considered to be central in male infertility by affecting sperm quality, function, and the integrity of sperm as well [1286]. Oxidative Stress may lead to sperm DNA damage and poorer sperm DNA integrity, which are associated with poor embryo development, miscarriage and infertility [1287, 1288]. Spermatozoa are vulnerable to OS and have limited capacity to repair damaged DNA. Oxidative stress is generally associated with poor lifestyle (e.g., smoking) and environmental exposure, and therefore antioxidant regimens and lifestyle interventions may reduce the risk of DNA fragmentation and improve sperm quality [1289]. However, this data has never been supported by RCTs. Furthermore, there are no standardised testing methods for reactive oxygen species (ROS) and the duration of antioxidant treatments. Although ROS can be measured by various assays (e.g., chemiluminescence), routine measurement of ROS testing should remain experimental until these tests are validated in randomised controlled studies [1290].

9.3.5.6 Outcomes from assisted reproductive technology and long-term health implications to the male and offspring

It is estimated that more than four million babies have been born with ART since the first baby conceived by IVF in 1978 [1291]. As the number of couples undergoing ART has increased [1292, 1293], safety concerns related to ART have been raised. Assisted reproductive technology-conceived offspring have poorer prenatal outcomes, such as lower birth weight, lower gestational age, premature delivery, and higher hospital admissions compared with naturally conceived offspring [1294, 1295]. However, the exact mechanisms resulting in these complications remain obscure. Birth defects have also been associated with children conceived via ART in numerous studies [1296-1298]. Furthermore, a 30%-40% increase of major malformations were linked with ART in meta-analyses [1299-1301]. However, debate still continues as to whether the increased risk of birth defects are related to parental age, ART or the intrinsic defects in spermatogenesis in infertile men [1302-1307].

As for the long-term outcomes, post-natal growth patterns are mostly not associated with ART [1296, 1308, 1309]. However, a number of studies showed that ART children are taller [1310, 1311]. This may be important as there is evidence showing that rapid weight gain during early childhood is linked with higher blood pressure levels in children conceived via ART [1312]. It is also suggested that ART-conceived children have similar

childhood illnesses and hospital services rates as compared with naturally conceived children [1313-1315]. Furthermore, some studies showed an increased risk for retinoblastoma [1316] and hepatoblastoma in children after ART. However, these studies have been challenged with other studies which have not supported these findings [1317]. The current evidence for cancer risk in children conceived with ART is inadequate and further studies are warranted [1318, 1319]. Finally, a number of epigenetic alterations seem to be caused by ART, which might be the molecular basis to a some complex traits and diseases [1320].

*9.3.6 **Imaging in the infertile male***

In addition to physical examination, a scrotal US may be helpful in: i) measuring testis volume; ii) assessing testicular anatomy and testicular structure in terms of US patterns, thus detecting signs of testicular dysgenesis often related to an impaired spermatogenesis (e.g., non-homogeneous testicular architecture and microcalcifications) and testis tumours; and, iii) finding indirect signs of obstruction (e.g., dilatation of rete testis, enlarged epididymis with cystic lesions, or absent vas deferens) [1186]. In clinical practice, Prader's orchidometer-derived testis volume is considered a reliable surrogate of US-measured testis volume, is easier to perform and is cost-effective [1185]. Nevertheless, scrotal US has a relevant role in testis volume assessment when Prader's orchidometer is unreliable (e.g., large hydrocele, inguinal testis, epididymal enlargement/fibrosis, thickened scrotal skin; small testis, where the epididymis is large in comparison to the total testis volume [1185, 1186]. US-patterns of testicular inhomogeneity [1321, 1322] is usually associated with ageing, although it has also been reported in association with testis atrophy and fibrosis [1186]. At present, a diagnostic testicular biopsy is not recommended when testicular inhomogeneity is detected [1321, 1322].

9.3.6.1 Testicular neoplasms

Scrotal US is widely used in everyday clinical practice in patients with oligozoospermia or azoospermia, as infertility has been found to be an additional risk factor for testicular cancer [1323, 1324]. In one study, men with infertility had an increased risk of testicular cancer (hazard rate [HR] 3.3). When infertility was refined according to individual semen parameters, oligozoospermic men had an increased risk of cancer compared with fertile control subjects (HR 11.9) [1325]. Furthermore, in a recent SR infertile men with testicular microcalcification (TM) were found to have an ~18-fold higher prevalence of testicular cancer [1326]. However, the utility of US as a routine screening tool in men with infertility to detect testis cancer remains a matter of debate [1323, 1324].

One issue in undertaking routine screening for testicular neoplasms in this cohort of patients is the risk of overdiagnosis and the increased detection of indeterminate lesions of the testis. These testicular lesions are often detected during the diagnostic work-up of infertile men and are difficult to characterise as benign or malignant based only upon US criteria, including size, vascularity and echogenicity.

A dichotomous cut-off of certainty in terms of lesion size that may definitely distinguish benign from malignant testicular masses is currently not available. However, in a recent study 81 patients with a lesion size < 10 mm on histology were identified and of these, 56 (69%) were benign lesions, although of note one-third were malignant. Overall, 100% of lesions < 5 mm in diameter were benign [1327]. Overall, available data suggest that the smaller the nodule, the less likely that it is malignant [1328], and lesions < 5 mm could be monitored, as they have a low probability of malignancy.

Small hypoechoic/hyperechoic areas may be diagnosed as intra-testicular cysts, focal Leydig cell hyperplasia, fibrosis and focal testis inhomogeneity after previous pathologic conditions. Hence, they require careful periodic US assessment and follow-up, especially if additional risk factors for malignancy are present (i.e., infertility, bilateral testicular microcalcifications, history of cryptorchidism, testicular atrophy, inhomogeneous parenchyma, history of testicular tumour, history of /contralateral tumour) [1186].

In the case of interval growth of a lesion and/or of the presence of additional risk factors for malignancy, testicular biopsy/surgery may be considered, although the evidence for adopting such a management policy is limited. In 145 men referred for azoospermia who underwent US before testicular biopsy, 49 (34%) had a focal sonographic abnormality; a hypoechoic lesion was found in 20 patients (14%), hyperechoic lesions were seen in 10 (7%); and, a heterogeneous appearance of the testicular parenchyma was seen in 19 patients (13%). Of 18 evaluable patients, 11 had lesions less than 5 mm all of which were confirmed to be benign. All other patients with hyperechoic or heterogeneous areas on US with subsequent tissue diagnoses were found to have benign lesions. The authors concluded that men with severe infertility who are found to have incidental testicular lesions and negative tumour markers and lesions less than 5 mm, may be observed with serial scrotal US examinations and enlarging lesions or those of greater dimension can be considered for histological biopsy [1329].

Other studies have suggested that if a testicular lesion is hyperechoic and non-vascular on colour Doppler US and associated with negative tumour markers, the likelihood of malignancy is low and consideration can be given to regular testicular surveillance, as an alternative to radical surgery. In contrast, hypoechoic and vascular lesions are more likely to be malignant [1330-1334]. However, most lesions cannot be characterised by US (indeterminate), and histology remains the only certain diagnostic tool. A multidisciplinary team discussion (MDT), including invasive diagnostic modalities, should therefore be considered in these patients.

The role of US-guided intra-operative frozen section analysis in the diagnosis of testicular cancer in indeterminate lesions remains controversial, although a number of authors have proposed its value in the intra-operative diagnosis of indeterminate testicular lesions [1335]. Whilst, the default treatment after patient counselling and MDT discussion may be radical orchidectomy, an US-guided biopsy with intra-operative frozen section analysis may be offered as an alternative to radical orchidectomy and potentially obviate the need for removal of the testis in a patient seeking fertility treatment. In those men who have severe abnormalities in semen parameters (e.g., azoospermia), a concurrent mTESE can also be performed at the time of diagnostic biopsy (panel recommendations).

In summary, if an indeterminate lesion is detected incidentally on US in an infertile male, a MDT discussion is highly recommended. Based upon the current literature, lesions < 5 mm in size are likely to be benign and serial US and self-examination can be performed. However, men with larger sized lesions (> 5 mm), which are hypoechoic or demonstrate vascularity, may be considered for open US-guided testis biopsy, testis sparing surgery with tumour enucleation for frozen section examination or radical orchidectomy. Therefore, in making a definitive treatment decision for surveillance versus intervention, consideration should be given to the size of the lesion, echogenicity, vascularity and previous history (e.g., cryptorchidism, previous history of germ cell tumour [GCT]). If intervention is to be undertaken in men with severe hypospermatogenesis (e.g., azoospermia), then a simultaneous TESE can be undertaken, along with sperm banking.

9.3.6.2 Varicocele

At present, the clinical management of varicocele is still mainly based on physical examination; nevertheless, scrotal color Doppler US is useful in assessing venous reflux and diamater, when palpation is unreliable and/or in detecting recurrence/persistence after surgery [1186]. Furthermore, definitive evidence of reflux and venous diameter may be utilised in the decision process to treat.

9.3.6.3 Transrectal US

For patients with a low seminal volume, acidic pH and severe oligozoospermia or azoospermia, in whom obstruction is suspected, scrotal and transrectal US are of clinical value in detecting CBAVD, presence or absence of the epididymis and/or seminal vesicles (SV) (e.g., abnormalities/agenesis). Likewise, TRUS has an important role in assessing obstructive azoospermia (OA) secondary to CBAVD or anomalies related to the ejaculatory ducts obstruction, such as ejaculatory duct cysts, SV dilatation or hypoplasia/atrophy, although retrograde ejaculation should be excluded as a differential diagnosis [1186, 1336].

*9.3.7 **Recommendations for the diagnostic work-up of male infertility***

Recommendations	Strength rating
Include a parallel assessment of the fertility status, including ovarian reserve, of the female partner during the diagnosis and management of the infertile male, since this might determine decision making in terms of timing and therapeutic strategies (e.g., assisted reproductive technology (ART) versus surgical intervention)	Strong
A complete medical history taking, physical examination and semen analysis are the essential components of male infertility evaluation.	Strong
Prader's orchidometer-derived testis volume is a reliable surrogate of ultrasound (US)-measured testis volume in everyday clinical practice.	Weak
Perform semen analyses according to the WHO Laboratory Manual for the Examination and Processing of Human Semen (5th edn) indications and reference criteria.	Strong
Perform a full andrological assessment in all men with couple infertility, particularly when semen analysis is abnormal in at least two consecutive tests.	Strong
In cases of oligozoospermia and azoospermia, a hormonal evaluation should be performed, including a serum total testosterone and Follicle Stimulating Hormone FSH/Luteinising Hormone.	Weak
Offer standard karyotype analysis and genetic counselling to all men with azoospermia and oligozoospermia (spermatozoa < 10 million/mL) for diagnostic purposes.	Strong
Do not test for Y-chromosome microdeletions in men with pure obstructive azoospermia as spermatogenesis will be normal.	Strong
Y-chromosome microdeletion testing may be offered in men with sperm concentrations of < 5 million sperm/mL, but should be mandatory in men with sperm concentrations of ≤ 1 million sperm/mL.	Strong
Testicular sperm extraction (any type) should not be attempted in patients with complete deletions that include the aZFa and aZFb regions, since they are a poor prognostic indicator for retrieving sperm at surgery.	Strong
Inform men with Yq microdeletion and their partners who wish to proceed with intracytoplasmic sperm injection (ICSI) that microdeletions will be passed to sons, but not to their daughters.	Strong
In men with structural abnormalities of the vas deferens (unilateral or bilateral absence with no renal agenesis), test the male and his partner for cystic fibrosis transmembrane conductance regulator gene mutations, which should include common point mutations and the 5T allele.	Strong
Provide genetic counselling in all couples with a genetic abnormality found on clinical or genetic investigation and in patients who carry a (potential) inheritable disease.	Strong
For men with Klinefelter Syndrome offer long-term endocrine follow-up and appropriate medical treatment.	Strong
Do not routinely use reactive oxygen species testing in the diagnosis and management of the male partner of an infertile couple.	Weak
Sperm DNA fragmentation testing should be performed in the assessment of couples with recurrent pregnancy loss from natural conception and ART or men with unexplained infertility.	Strong
Perform scrotal ultrasound in patients with infertility, as there is a higher risk of testis cancer.	Weak
A multidisciplinary team discussion concerning invasive diagnostic modalities (e.g., US-guided testis biopsy with frozen section versus radical orchidectomy versus surveillance) should be considered in infertile men with US-detected indeterminate testicular lesions, especially if additional risk factors for malignancy are present.	Weak
Perform transrectal ultrasound if a partial or complete distal obstruction is suspected.	Strong
Consider imaging for renal abnormalities in men with structural abnormalities of the vas deferens and no evidence of cystic fibrosis transmembrane conductance regulator abnormalities.	Strong

9.4 Special Conditions and Relevant Clinical Entities

*9.4.1 **Cryptorchidism***

Cryptorchidism is the most common congenital abnormality of the male genitalia; at one year of age nearly 1% of all full-term male infants have cryptorchidism [1337]. Approximately 30% of undescended testes are non-

palpable and may be located within the abdominal cavity. This guideline will only deal with the management of cryptorchidism in adults.

9.4.1.1 Classification

The classification of cryptorchidism is based on the duration of the condition and the anatomical position of the testis. If the undescended testicle has been identified from birth then this is termed congenital whilst the diagnosis of acquired is used in males that have been previously noted to have testicles situated within the scrotum. Cryptorchidism is categorised on whether it is bilateral or unilateral and the location of the testicle (inguinal, intra-abdominal or ectopic).

Studies have shown that treatment of congenital and acquired cryptorchidism results in similar hormone profiles, semen analysis and testicular volumes [1338, 1339]. However, testicular volume and hormone function have been reported to be reduced in adults treated with congenital bilateral cryptorchidism compared to unilateral cryptorchidism [1340].

9.4.1.1.1 Aetiology and pathophysiology

It has been postulated that cryptorchidism may be a part of the so-called testicular dysgenesis syndrome (TDS), which is a developmental disorder of the gonads caused by environmental and/or genetic influences early in pregnancy, including exposure to endocrine disrupting chemicals. Besides cryptorchidism, TDS includes hypospadias, reduced fertility, increased risk of malignancy, and Leydig/Sertoli cell dysfunction [1341]. Cryptorchidism has also been linked with maternal gestational smoking [1342] and premature birth [1343].

9.4.1.1.2 Pathophysiological effects in maldescended testes

9.4.1.1.2.1 Degeneration of germ cells

The degeneration of germ cells in maldescended testes is apparent even after the first year of life and varies, depending on the position of the testis [1344]. During the second year, the number of germ cells declines. Early treatment is therefore recommended (surgery should be performed within the subsequent year) to conserve spermatogenesis and hormone production, as well as to decrease the risk for tumours [1345]. Surgical treatment is the most effective. Meta-analyses on the use of medical treatment with GnRH and hCG have demonstrated poor success rates [1346, 1347]. It has been reported that hCG treatment may be harmful to future spermatogenesis therefore, the Nordic Consensus Statement on treatment of undescended testes does not recommend it use on a routine basis [1348]. See also the EAU Guidelines on Paediatric Urology [1349].

There is increasing evidence to suggest that in cases of a unilateral undescended testicle, the contralateral normal descended testicle may also have structural abnormalities, including smaller volume, softer consistency and reduced markers of future fertility potential (spermatogonia/tubule ratio and a dark spermatogonia) [1338, 1350]. This implies that unilateral cryptorchidism may affect the contralateral testis and patients and parents should be counselled appropriately.

9.4.1.1.2.2 Relationship with fertility

Semen parameters are often impaired in men with a history of cryptorchidism [1351]. Early surgical treatment may have a positive effect on subsequent fertility [1352]. In men with a history of unilateral cryptorchidism, paternity is almost equal (89.7%) to that in men without cryptorchidism (93.7%). In men with bilateral cryptorchidism, oligozoospermia can be found in 31% and azoospermia in 42%. In cases of bilateral cryptorchidism, the rate of paternity falls to 35-53% [1353]. It is also important to screen for hypogonadism, as this is a potential long-term sequelae of cryptorchidism and could contribute to impaired fertility and potential problems such as testosterone deficiency and MetS [1354].

9.4.1.1.2.3 Germ cell tumours

As a component of the TDS, cryptorchidism is a risk factor for testicular cancer and is associated with testicular microcalcifications and intratubular germ cell neoplasia *in situ* (GCNIS), formerly known as carcinoma *in situ* (CIS) of the testes. In 5-10% of testicular cancers, there is a history of cryptorchidism [1355]. The risk of a germ cell tumour is 3.6-7.4 times higher than in the general population and 2-6% of men with a history of cryptorchidism will develop a testicular tumour [1337]. Orchidopexy performed before the onset of puberty has been reported to decrease the risk of testicular cancer [1356]. However, there is evidence to suggest that even men who undergo early orchidopexy still harbour a higher risk of testicular cancer than men without cryptorchidism [1357]. Therefore all men with a history of cryptorchidism should be warned that they are at increased risk of developing testis cancer and should perform regular testicular self-examination [1358].

9.4.1.2 Disease management

9.4.1.2.1 Hormonal treatment

Human chorionic gonadotropin or GnRH is not recommended for the treatment of cryptorchidism in adulthood. Although some studies have recommended the use of hormonal stimulation as an adjunct to orchidopexy to improve fertility preservation, there is a lack of long-term data and also concerns regarding impairment to spermatogenesis with the use of these drugs [1359].

9.4.1.2.2 Surgical treatment

In adolescence removal of an intra-abdominal testis (with a normal contralateral testis) can be recommended, because of the risk of malignancy [1360]. In adults, with a palpable undescended testis and a normal functioning contralateral testis (i.e., biochemically eugonadal), an orchidectomy may be offered in this setting as there is evidence that the undescended testicle confers a higher risk of GCNIS and future development of GCT [1361] and regular testicular self-examination is not an option in these patients. In those patients with unilateral undescended testis (UDT) and impaired testicular function on the contralateral testis as demonstrated by biochemical hypogonadism and/or impaired sperm production (infertility), an orchidopexy may be offered in this setting to preserve androgen production and fertility if surgically feasible. However, multiple biopsies of the UDT are recommended at the time of orchidopexy to exclude intra-testicular GCNIS as a prognostic indicator of future development of GCT (panel consensus opinion). As indicated above, the correction of bilateral cryptorchidism, even in adulthood, can lead to sperm production in previously azoospermic men and therefore may be considered in these patients, if surgically feasible and or in patients who place a high utility on fertility preservation [1362]. Vascular damage is the most severe complication of orchidopexy and can cause testicular atrophy in 1-2% of cases. In men with non-palpable testes, the post-operative atrophy rate was 12% in those cases with long vascular pedicles that enabled scrotal positioning. Post-operative atrophy in staged orchidopexy has been reported in up to 40% of patients [1363]. At the time of orchidectomy in the treatment of GCT, biopsy of the contralateral testis should be offered to patients at high risk for GCNIS (i.e. history of cryptorchidism, < 12 mL. testicular volume, poor spermatogenesis [1364]).

9.4.1.3 Summary of evidence recommendations for cryptorchidism

Summary of evidence	**LE**
Cryptorchidism is multifactorial in origin and can be caused by genetic factors and endocrine disruption early in pregnancy.	2a
Cryptorchidism is often associated with testicular dysgenesis and is a risk factor for infertility and GCTs and patients should be counselled appropriately.	2b
Paternity in men with unilateral cryptorchidism is almost equal to men without cryptorchidism.	1B
Bilateral cryptorchidism significantly reduces the likelihood of paternity and patients should be counselled appropriately.	1B

Recommendations	**Strength rating**
Do not use hormonal treatment for cryptorchidism in post-pubertal men.	Strong
If undescended testes are corrected in adulthood, perform simultaneous testicular biopsy, for the detection of intratubular germ cell neoplasia *in situ* (formerly carcinoma *in situ*).	Strong
Men with unilateral undescended testis and normal hormonal function/spermatogenesis should be offered orchidectomy.	Strong
Men with unilateral or bilateral undescended testis with biochemical hypogonadism and or spermatogenic failure (i.e., infertility) may be offered unilateral or bilateral orchidopexy, if technically feasible.	Weak

9.4.2 ***Germ cell malignancy and male infertility***

Testicular germ cell tumour (TGCT) is the most common malignancy in Caucasian men aged 15-40 years, and affects approximately 1% of sub-fertile men [1365]. The lifetime risk of TGCT varies between ethnic groups and countries. The highest annual incidence of TGCT occurs in Caucasians, and varies from 10/100,000 (e.g., in Denmark and Norway) to 2/100,000 (e.g., in Finland and the Baltic countries). Generally, seminomas and nonseminomas are preceded by GCNIS, and untreated GCNIS will eventually progress to invasive cancer [1366-1368]. There has been a general decline in male reproductive health and an increase in testicular cancer seen in western countries [1369, 1370]. In almost all countries with reliable cancer registries, the incidence of testicular cancer has increased [1258, 1371]. This has been postulated to be related to the so-called TDS, which is a developmental disorder of the testes caused by environmental and/or genetic influences in

pregnancy. As detailed above, the adverse sequelae of TDS include cryptorchidism hypospadias, infertility and an increased risk of testicular cancer [1341]. Endocrine disrupting chemicals have also been associated with sexual dysfunction [1372] and abnormal semen parameters [1373]. These cancers arise from premalignant gonocytes or GCNIS [1374]. Testicular microcalcification, seen on US, can be associated with TGCT and GCNIS of the testes [1326, 1375, 1376].

9.4.2.1 Testicular germ cell cancer and reproductive function

Overall, sperm, cryopreservation is considered standard practice in patients with cancer, not only with testicular cancer [1377, 1378]. As such, it is important to stress that all men with cancer must be offered sperm cryopreservation prior to the therapeutic use of gonadotoxic agents or ablative surgery which may impair spermatogenesis or ejaculation (i.e., chemotherapy; radiation therapy; retroperitoneal surgery).

Men with TGCT have decreased semen quality, even before cancer treatment. Azoospermia has been observed in 5-8% of men with TGCT [1379] and oligospermia in 50% [1380]. Given that the average ten-year survival rate for testicular cancer is 98% and it is the most common cancer in men of reproductive potential, it is mandatory to include counselling regarding fertility preservation prior to any gonadotoxic treatment [1380, 1381]. Semen analysis and cryopreservation is therefore recommended prior to any gonadotoxic cancer treatment and all patients should be offered cryopreservation of ejaculated sperm or sperm extracted surgically (e.g., c/mTESE) if shown to be azoospermic or severely oligozoospermic. Given the fact that a significant number of men with testis cancer at the time of first presentation will have severe semen abnormalities (i.e., severe oligozoospermia/azoospermia) even prior to (any) treatment [1374], it is recommended that men should undergo sperm cryopreservation prior to orchidectomy. As mentioned above, in those who are either azoospermic or severely oligozospermic this will allow an opportunity to perform TESE prior to further potential gonadotoxic/ablative surgery [1380]. The use of cryopreservation has been demonstrated to be the most cost effective strategy for fertility preservation in patients undergoing potential gonadotoxic treatments [1382, 1383]. In cases of azoospermia, testicular sperm may be recovered to safeguard patient's fertility (Onco-TESE) potential. The surgical principles in Onco-TESE do not differ from the technique of mTESE for men with infertility (e.g., NOA) [1384, 1385]. In this context, referral to an urologist adept in microsurgery is desirable with facilities for sperm cryopreservation.

Rates of under-utilisation of semen analysis and sperm cryopreservation have been reported to be high; resulting in the failure to identify the azoospermic or severely oligozoospermic patient at diagnosis who may eventually benefit from fertility-preserving procedures (e.g., Onco-mTESE at the time of orchidectomy). Therefore, counselling about fertility preservation is a priority and needs to be broached earlier in men with testis cancer [1380]. There are controversial arguments that performing cryopreservation prior to orchidectomy may delay subsequent treatment and have an adverse impact on survival. In this context, orchidectomy should not be unduly delayed if there are no facilities for cryopreservation or there is a potential delay in treatment.

Treatment of TGCT can result in additional impairment of semen quality [1386] and increased sperm aneuploidy up to two years following gonadotoxic therapy [1387]. Chemotherapy is also associated with DNA damage and an increased DNA fragmentation rate [1388]. However, sperm aneuploidy levels will often decline to pre-treatment levels 18-24 months post treatment [1387] and several studies reviewing the offspring of cancer survivors has not shown a significant increased risk of genetic abnormalities in the context of chemotherapy and radiotherapy treatment [1389].

In addition to spermatogenic failure, patients with TGCT have Leydig cell dysfunction, even in the contralateral testis [1390]. The risk of hypogonadism may therefore be increased in men treated for TGCT. The measurement of pre-treatment levels of testosterone, SHBG, LH and oestradiol may help to stratify those patients at increased risk of hypogonadism and provide a baseline for post-treatment hypogonadism. Men who have had TGCT and have low normal androgen levels should be advised that they may be at increased risk of developing hypogonadism, as a result of an age-related decrease in testosterone production and could potentially develop MetS; there is no current long term data supporting this. The risk of hypogonadism is increased in the survivors of testis cancer and serum testosterone levels should be evaluated during the management of these patients [1391]. However, this risk is greatest at six to twelve months post-treatment and suggests that there may be some improvement in Leydig cell function post treatment and it is therefore reasonable to delay initiation of TRT, until the patient shows continuous signs or symptoms of testosterone deficiency [1366]. The risk of low libido and ED is also increased in TGCT patients [1392]. Furthermore, patients treated for TGCT are also at increased risk of CVD [1388]. Therefore, patients may require a MDT approach and in this context, survivorship programmes incorporating a holistic view of patients psychological, medical and social needs could be beneficial to the patient. In those patients who place a high utility on fertility potential, the use of TRT in men

with symptoms suggestive for TDS will need to be balanced with worsening spermatogenesis. In these patients consideration can be given to the use of SERM (e.g., clomiphene) or gonadotrophin analogues (e.g., hCG), although these are off label treatments in this particular clinical setting.

9.4.2.2 Testicular microcalcification

Microcalcification inside the testicular parenchyma can be found in 0.6-9% of men referred for testicular US [1393, 1394]. Although the true incidence of testicular microcalcification (TM) in the general population is unknown, it is most probably rare. Ultrasound findings of TM have been associated in men with TGCT, cryptorchidism, infertility, testicular torsion and atrophy, Klinefelter's syndrome, hypogonadism, male pseudohermaphroditism and varicocele [1395]. The incidence reported seems to be higher with high-frequency US machines [1396]. The relationship between TM and infertility is unclear, but may relate to dysgenesis of the testes, with degenerate cells being sloughed inside an obstructed seminiferous tubule and failure of the Sertoli cells to phagocytose the debris. Subsequently, calcification with hydroxyapatite occurs. Testicular microcalcification is found in testes at risk of malignant development, with a reported incidence of TM in men with TGCT of 6-46% [1397-1399]. A recent SR and meta-analysis of case-control studies indicated that the presence of TM is associated with a ~18-fold higher odds ratio for testicular cancer in infertile men (pooled OR:18.11, 95%CI: 8.09, 40.55; $p < 0.0001$) [1326].

Testicular microcalcification should therefore be considered pre-malignant in this setting and patients counselled accordingly. Testicular biopsies from men with TM have found a higher prevalence of GCNIS, especially in those with bilateral microcalcifications [1400]. However, TM can also occur in benign testicular conditions and the microcalcification itself is not malignant. Therefore, the association of TM and TGCT is controversial and the challenge is to identify those men at risk of harbouring GCNIS and future risk of TGCT. Further investigation of the association between TM and GCNIS will require testicular biopsies in large series of men without signs of TGCT with or without risk factors for TGCT. However, the clinician and patient should be reassured that testicular cancer will not develop in the majority of men with asymptomatic TM [1376] and available data indicates that only men in whom TM is found by US, and who have an increased risk of TGCT, should be offered testicular biopsy to exclude GCNIS. Men potentially at high-risk of harbouring or developing GCNIS includes men with infertility, atrophic testes, undescended testes, a history of TGCT, and contralateral TM and it has been suggested that men with these risk factors could be offered testicular biopsy [1370, 1375]. The normal mean testicular volume is estimated to range between 12-30 mL and less than 12 mL is considered small [1393]. Patients with a history of TGCT and TM in the contralateral testis and sub-fertile patients have been demonstrated to have an increased risk of GCNIS [1376], whilst there are only a few studies showing a further increase in GCNIS with TM in the context of cryptorchidism [1370, 1394, 1401]. A useful algorithm has been proposed [1370] to stratifying those patients at increased risk of GCNIS who may benefit from testicular biopsy. However, when undertaking a biopsy in this setting the full risks and complications of adopting this strategy must be explained to the patient. With the lack of availability of large cohort studies, these recommendations must be treated with caution given the risk of overtreatment (i.e. biopsy) in these patients.

Decastro *et al.* [1402] suggested that testicular cancer will not develop in the majority of men with TM (98.4%) during a five-year follow-up. As such, an extensive screening program would only benefit men at significant risk. In this context it would be prudent to advise those patients with TM and risk factors for developing testicular cancer to at least undergo regular testicular examination. It has been suggested that these patients could also be offered annual physical examination by a urologist and US follow-up, although follow up protocols may be difficult to implement in this invariably young cohort of patients [1395]. As testicular atrophy and infertility have an association with testicular cancer, some authors recommend biopsy or follow-up US if TM is seen [1370]. However, the majority of patients who are azoospermic will be undergoing therapeutic biopsy (i.e. sperm retrieval) and therefore a definitive diagnosis can be made and there is a lack of evidence demonstrating a higher prevalence of testicular cancer in patients with both TM and testicular atrophy. In those patients with incidental TM, the risk of GCNIS will be low and a logical approach would be to instruct patients to perform regular testicular self-examination.

9.4.2.3 Recommendations for germ cell malignancy and testicular microcalcification

Recommendations	Strength rating
Men with testicular microcalcification (TM) should learn to perform self-examination even without additional risk factors, as this may result in early detection of testicular germ cell tumour (TGCT).	Weak
Do not perform testicular biopsy, follow-up scrotal ultrasound, measure biochemical tumour markers, or abdominal or pelvic computed tomography, in men with isolated TM without associated risk factors (e.g., infertility, cryptorchidism, testicular cancer, and atrophic testis).	Strong
Testicular biopsy may be offered in infertile men with TM, who belong to one of the following higher risk groups: spermatogenic failure (infertility), bilateral TM, atrophic testes (less than 12 mL), history of undescended testes and TGCT.	Weak
If there are suspicious findings on physical examination or ultrasound in patients with TM with associated lesions, perform inguinal surgical exploration with testicular biopsy or offer orchidectomy after multidisciplinary meeting and discussion with the patient.	Strong
Men treated for TGCT are at increased risk of developing hypogonadism, sexual dysfunction and cardiovascular (CV) risk. Men should be managed in a multidisciplinary team setting with a dedicated late effects clinic.	Weak
Sperm cryopreservation should be performed prior to planned orchidectomy, since men with testis cancer may have significant semen abnormalities (including azoospermia).	Weak
Men with testis cancer and azoospermia or severe abnormalities in their semen parameters may be offered onco-testicular sperm extraction at the time of radical orchidectomy.	Weak

9.4.3 ***Varicocele***

Varicocele is a common genital abnormality, which may be associated with the following andrological conditions:

- male subfertility;
- failure of ipsilateral testicular growth and development;
- symptoms of pain and discomfort;
- hypogonadism.

9.4.3.1 Classification

The following classification of varicocele [1176] is useful in clinical practice:

- Subclinical: not palpable or visible at rest or during Valsalva manoeuvre, but can be shown by special tests (Doppler US studies).
- Grade 1: palpable during Valsava manoeuvre.
- Grade 2: palpable at rest.
- Grade 3: visible and palpable at rest.

Overall, the prevalence varicocele in one study was 48%. Of 224 patients, 104 had unilateral, 120 had bilateral varicoceles; 62 (13.30%) were grade 3, 99 (21.10%) were grade 2, and 63 (13.60%) were grade 1 [1403, 1404]. Worsening semen parameters are associated with a higher grade of varicocele and age [1405, 1406].

9.4.3.2 Diagnostic evaluation

The diagnosis of varicocele is made by physical examination and if this examination is inconclusive scrotal Doppler US is indicated [1176, 1407]. A number of radiological thresholds for venous diameter on US are used to diagnose significant varicoceles, although multiple spermatic veins > 3 mm in the upright position and during the Valsalva manoeuvre correlate with the presence of a clinically significant varicocele [1408a].

9.4.3.3 Basic considerations

9.4.3.3.1 Varicocele and fertility

Varicocele is present in almost 15% of the normal male population, in 25% of men with abnormal semen analysis and in 35-40% of men presenting with infertility (1,3,7,9). The incidence of varicocele among men with primary infertility is estimated at 35-44%, whereas the incidence in men with secondary infertility is 45-81% [1176, 1409].

The exact association between reduced male fertility and varicocele is unknown. Increased scrotal temperature, hypoxia and reflux of toxic metabolites can cause testicular dysfunction and infertility due to increased OS and DNA damage [1409].

A meta-analysis showed that improvements in semen parameters are usually observed after surgical correction in men with abnormal parameters [1408b]. Varicocelectomy can also reverse sperm DNA damage and improve OS levels [1409, 1410].

9.4.3.3.2 Varicocelectomy

Varicocele repair has been a subject of debate for several decades. A meta-analysis of RCTs and observational studies in men with only clinical varicoceles showed that surgical varicocelectomy significantly improves semen parameters in men with abnormal semen parameters, including men with NOA with hypo-spermatogenesis or late maturation (spermatid) arrest on testicular pathology [1411-1415]. Moreover, pain resolution after varicocelectomy occurs in 48-90% of the patients [1416].

In RCTs varicocele repair in men with a subclinical varicocele was found to be ineffective in increasing the chances of spontaneous pregnancy [1417]. Also, in randomised studies that included mainly men with normal semen parameters no benefit was found in favour of treatment over observation. A Cochrane review from 2012 concluded that there is evidence to suggest that treatment of a varicocele in men from couples with otherwise unexplained subfertility may improve a couple's chance for spontaneous pregnancy [1418]. In two recent meta-analysis of RCTs comparing treatment to observation in men with a clinical varicocele, oligozoospermia and otherwise unexplained infertility, the analyses favoured treatment, with a combined OR of 2.39-4.15 (95% CI 1.56 to 3.66) (95% CI, 2.31 to 7.45) [1415, 1418]. A recent meta-analysis has reported that varicocelectomy may improve outcomes following ART in oligozoospermic men with an OR of 1.69 (95% CI 0.95 to 3.02) [1419].

9.4.3.3.3 Prophylactic varicocelectomy

In adolescents with a varicocele, there is a significant risk of over-treatment since most adolescents with a varicocele will have no problem achieving pregnancy later in life [1420]. Prophylactic treatment is only advised in case of documented testicular growth deterioration confirmed by serial clinical or Doppler US examinations and/or abnormal semen analysis [1421, 1422].

More novel considerations for varicocelectomy are patients with NOA, hypogonadism and DNA damage are described below:

Varicocelectomy and NOA

A number of studies have suggested that varicocelectomy may lead to sperm appearing in the ejaculate in men with azoospermia. In one such study, microsurgical varicocelectomy in men with NOA men led to sperm in the ejaculate post-operatively with an increase in ensuing natural or assisted pregnancies [1423]. There were further beneficial effects on sperm retrieval rates and ICSI outcomes. Meta-analyses have further corroborated these findings; 468 patients diagnosed with NOA and varicocele underwent surgical varicocele repair or percutaneous embolisation. In patients who underwent varicocelectomy, sperm retrieval rates (SRR) increased compared to those without varicocele repair (OR: 2.65; 95% CI: 1.69-4.14; $p< 0.001$). In 43.9% of the patients (range: 20.8%-55.0%), sperm were found in postoperative ejaculate. These findings indicate that varicocelectomy in patients with NOA and clinical varicocele is associated with improved SRR and overall 44% of the treated men will have sperm in the ejaculate and may avoid sperm retrieval. However, the quality of evidence available is low and the risks and benefits of varicocele repair must be discussed fully with the patient with NOA and a clinically significant varicocele prior to embarking upon treatment intervention [1413].

Varicocelectomy and hypogonadism

Evidence would also suggest that men with clinical varicoceles who are hypogonadal may benefit from varicocele intervention. In one meta-analysis studying the efficacy of varicocele intervention by comparing the pre-operative and post-operative serum testosterone, 712 patients were included for analysis. The combined analysis of seven studies demonstrated that the mean post-operative serum testosterone improved by 34.3 ng/dL (95% CI: 22.57-46.04, $p < 0.00001$, $I^2 = 0.0\%$) compared with their pre-operative levels. In an analysis of surgery versus untreated control results showed that mean testosterone among hypogonadic patients increased by 105.65 ng/dL (95% CI: 77.99-133.32), favouring varicocelectomy [1424]. However, results must be treated with caution and adequate cost benefit analysis must be undertaken to determine the risks and benefits of surgical intervention over TRT in this setting. Whilst, varicocelectomy may be offered in hypogonadal men with clinically significant varicoceles, patients must be advised that the full benefits of treatment in this setting must be further evaluated with prospective randomised controlled studies.

9.4.3.3.4 Varicocelectomy for assisted reproductive technology and for raised DNA fragmentation

Varicocelectomy can improve sperm DNA integrity, with a mean difference of -3.37% (95% CI, -2.65 to -4.09) [1425]. There is now increasing evidence that varicocele treatment may improve DNA fragmentation

and outcomes from ART [1419, 1420]. As a consequence, more recently it has been suggested that the indications for varicocele intervention should be expanded to also include men with raised DNA fragmentation. If a patient has failed ART (e.g., failure of implantation, embryogenesis or recurrent pregnancy loss) there is an argument that if DNA damage is raised, consideration could be given to varicocele intervention after extensive counselling [1426] and exclusion of other causes of raised DNA fragmentation [1420, 1427]. The dilemma is whether varicocele treatment is indicated in men with raised DNA fragmentation and normal semen parameters.

In a meta-analysis study of non-azoospermic infertile men with clinical varicocele by Estevez *et al.*, four retrospective studies were included of men undergoing ICSI, and included 870 cycles (438 subjected to ICSI with prior varicocelectomy, and 432 without prior varicocelectomy). There was a significant increase in the clinical pregnancy rates (OR = 1.59, 95% CI: 1.19-2.12, I^2 = 25%) and live birth rates (OR = 2.17, 95% CI: 1.55-3.06, I^2 = 0%) in the varicocelectomy group compared to the group subjected to ICSI without previous varicocelectomy. A further study [1419] evaluated the effects of varicocele repair and its impact on pregnancy and live birth rates in infertile couples undergoing ART in male partners with oligospermia or azoospermia and a varicocele. In 1,241 patients, a meta-analysis demonstrated that varicocelectomy improved live birth rates for the oligospermic (OR = 1.699) men and combined oligospermic/azoospermic groups (OR = 1.761). Pregnancy rates were higher in the azoospermic group (OR = 2.336) and combined oligospermic/azoospermic groups (OR = 1.760). Live birth rates were higher for patients undergoing IUI after intervention (OR = 8.360).

9.4.3.4 Disease management

Several treatments are available for varicocele (Table 34). Current evidence indicates that microsurgical varicocelectomy is the most effective method among the different varicocelectomy techniques [1420, 1428]. Unfortunately, there are no large prospective RCTs comparing the efficacy of the various interventions for varicocele. However, microsurgical repair results in fewer complications and lower recurrence rates compared to the other techniques based upon case series [1429]. This procedure, however, requires microsurgical training. The various other techniques are still considered viable options, although recurrences and hydrocele formation appear to be higher [1430].

Radiological techniques (sclerotherapy and embolisation) are minimally invasive widely used approaches, although higher recurrence rates compared to microscopic varicocelectomy have been reported (4-27%) [1409]. Robot-assisted varicocelectomy has similar success rate compared to the microscopic varicocelectomy technique, although larger prospective randomised studies are needed to establish the most effective method [1431-1433].

Table 34: Recurrence and complication rates associated with treatments for varicocele

Treatment	Ref.	Recurrence/ Persistence %	Overall complications	Specific Complications
Antegrade sclerotherapy	[1434, 1435]	5-9	Hydrocele (5.5%), haematoma, infection, scrotal pain, testicular atrophy, epididymitis	Technical failure 1-9%, left-flank erythema.
Retrograde sclerotherapy	[1436, 1437]	6-9.8	Hydrocele (3.3%) wound infection, scrotal pain	Technical failure 6-7.5%, adverse reaction to contrast medium, flank pain, persistent thrombophlebitis, venous perforation
Retrograde embolisation	[1436, 1438]	3-11	Hydrocele (10%) haematoma, wound infection	Technical failure 7-27%, pain due to thrombophlebitis, radiological complications (e.g., reaction to contrast media), misplacement or migration of coils (to femoral vein or right atrium), retroperitoneal haemorrhage, fibrosis, ureteric obstruction, venous perforation
Open operation				
Scrotal operation		-	Testicular atrophy, arterial damage with risk of devascularisation and testicular gangrene, scrotal haematoma, post-operative hydrocele	
Inguinal approach	[1439, 1440]	2.6-13	Hydrocele (7.3%), testicular atrophy, epididymo-orchitis, wound complications	Post-operative pain due to incision of external oblique fascia, genitofemoral nerve damage
Open retroperitoneal high ligation	[1428, 1441]	15-29	Hydrocele (5-10%), testicular atrophy, scrotal edema	External spermatic vein ligation failure
Microsurgical inguinal or subinguinal	[1429, 1439, 1442, 1443]	0.4	Hydrocele (0.44%), scrotal haematoma	
Laparoscopy	[1406, 1428, 1429, 1444, 1445]	3-6	Hydrocele (7-43%) epididymitis, wound infection, testicular atrophy due to injury of testicular artery, bleeding	External spermatic vein ligation failure, intestinal, vascular and nerve damage; pulmonary embolism; pneumoscrotum; peritonitis; post-operative pain in right shoulder (due to diaphragmatic stretching during pneumoperitoneum)

9.4.3.5 Summary of evidence and recommendations for varicocele

Summary of evidence	LE
The presence of varicocele in some men is associated with progressive testicular damage from adolescence onwards and a consequent reduction in fertility.	2a
Although the treatment of varicocele in adolescents may be effective, there is a significant risk of over-treatment: the majority of boys with a varicocele will have no fertility problems later in life.	3
Varicocele repair may be effective in men with abnormal semen parameters, a clinical varicocele and otherwise unexplained male factor infertility.	1a
Although there are no prospective randomised studies evaluating this, meta-analysis suggest that varicocele repair may lead to sperm appearing in the ejaculate in men with non-obstructive azoospermia	2
Microscopic approach (inguinal/subinguinal) may have lower recurrence and complications rates than non-microscopic approaches (retroperitoneal and laparoscopic), although no RCTs are available yet.	2a
Varicocele is associated with raised DNA fragmentation and intervention has been shown to reduce DNA fragmentation	2a

Recommendations	Strength rating
Treat varicocele in adolescents with ipsilateral reduction in testicular volume and evidence of progressive testicular dysfunction.	Weak
Do not treat varicocele in infertile men who have normal semen analysis and in men with a subclinical varicocele.	Weak
Treat infertile men with a clinical varicocele, abnormal semen parameters and otherwise unexplained infertility in a couple where the female partner has good ovarian reserve to improve fertility rates.	Strong
Varicocelectomy may be considered in men with raised DNA fragmentation with otherwise unexplained infertility or who have suffered from failed assisted reproductive techniques, including recurrent pregnancy loss, failure of embryogenesis and implantation.	Weak

*9.4.4 **Male accessory gland infections and infertility***

9.4.4.1 Introduction

Infections of the male urogenital tract are potentially curable causes of male infertility [1446-1448]. The WHO considers urethritis, prostatitis, orchitis and epididymitis to be male accessory gland infections (MAGIs) [1446]. The effect of symptomatic or asymptomatic infections on sperm quality is contradictory [1449]. A SR assessing the relationship between sexually transmitted diseases, such as *Chlamydia trachomatis*, genital mycoplasmas, *Neisseria gonorrhoeae, Trichomonas vaginalis* and viral infections, and infertility was unable to draw a strong association between STDs and male infertility due to the limited quality of reported data [1450].

9.4.4.2 Diagnostic evaluation

9.4.4.2.1 Semen analysis

Semen analysis (see Section 9.3.2) clarifies whether the prostate is involved as part of a generalised MAGI and provides information regarding sperm quality. In addition, leukocyte analysis allows differentiation between inflammatory and non-inflammatory chronic pelvic pain syndrome (CP/CPPS) (NIH IIa versus NIH 3b National Institutes of Health classification for CP/CPPS).

9.4.4.2.2 Microbiological findings

After exclusion of UTI (including urethritis), > 10^6 peroxidase-positive white blood-cells (WBCs) per millilitre of ejaculate indicate an inflammatory process. In these cases, a semen culture or PCR analysis should be performed for common urinary tract pathogens. A concentration of > 10^3 CFU/mL urinary tract pathogens in the ejaculate is indicative of significant bacteriospermia [1451]. The sampling should be delivered the same day to the laboratory because the sampling time can influence the rate of positive micro-organisms in semen and the frequency of isolation of different strains [1452]. The ideal diagnostic test for isolating *C. trachomatis* in semen has not yet been established [1453], but the most accurate method is PCR analysis [1454-1456].

Historical data showed that *Ureaplasma urealyticum* is pathogenic only in high concentrations (> 10^3 CFU/mL ejaculate). Less than 10% of samples analysed for ureaplasma exceeded this concentration [1457]. Normal colonisation of the urethra hampers the significance of mycoplasma-associated urogenital infections, using samples such as the ejaculate [1458].

A recent meta-analysis indicates that *Ureaplasma parvum* and *Mycoplasma genitalium* are not associated with male infertility, but a significant relationship existed between *Ureaplasma urealyticum* (OR 3.03 95% CI: 1.02-8.99) and *Mycoplasma hominis* (OR 2.8; 95% CI: 0.93- 3.64) [1459].

The prevalence of Human papilloma virus (HPV) in the semen ranges from 2-31% in the general population and is higher in men with unexplained infertility (10-35,7%) [1460,1461]. Recent systematic reviews have reported an association between male infertility, poorer pregnancy outcomes and semen HPV positivity [1462-1464]. However, data still needs to be prospectively validated to clearly define the clinical impact of HPV infection in semen. Additionally, seminal presence of Herpes Simplex virus (HSV)-2 in infertile men may be associated with lower sperm quality compared to HSV-negative infertile men [1449]. However, it is unclear if anti-viral therapy improves fertility rates in these men.

9.4.4.2.3 White blood cells

The clinical significance of an increased concentration of leukocytes in the ejaculate is controversial [1465]. Although leukocytospermia is a sign of inflammation, it is not necessarily associated with bacterial or viral infections, and therefore cannot be considered a reliable indicator [1466]. According to the WHO classification, leukocytospermia is defined as > 10^6 WBCs/mL. Only two studies have analysed alterations of WBCs in the ejaculate of patients with proven prostatitis [1467, 1468]. Both studies found more leukocytes in men with prostatitis compared to those without inflammation (CPPS, type NIH 3b). Furthermore, leukocytospermia should be further confirmed by performing a peroxidase test on the seminal analysis. There is currently no evidence that treatment of leukocytospermia alone without evidence of infective organisms will improve conception rates [1469].

9.4.4.2.4 Sperm quality

The deleterious effects of chronic prostatitis (CP/CPPS) on sperm density, motility and morphology has been demonstrated in a recent SR based on case-controlled studies [1470]. Both *C. trachomatis* and *Ureoplasma spp*. can cause decreased sperm density, motility, altered morphology and increased DNA damage. HPV can also induce changes in sperm density, motility and DNA damage [1460, 1461]. *Mycoplasma spp*. can cause decreased motility and development of antisperm antibodies [1449].

9.4.4.2.5 Seminal plasma alterations

Seminal plasma elastase is a biochemical indicator of polymorphonuclear lymphocyte activity in the ejaculate [1448, 1471, 1472]. Various cytokines are involved in inflammation and can influence sperm function. Several studies have investigated the association between interleukin (IL) concentration, leukocytes, and sperm function through different pathways but no correlations have been found [1473-1475].

The prostate is the main site of origin of IL-6 and IL-8 in the seminal plasma. Cytokines, especially IL-6, play an important role in the male accessory gland inflammatory process [1476]. However, elevated cytokine levels do not depend on the number of leukocytes in expressed prostatic secretion (EPS) [1477].

9.4.4.2.6 Glandular secretory dysfunction

The secretory function of the prostate gland can be evaluated by measuring seminal plasma pH, citric acid, or γ-glutamine transpeptidase levels; the seminal plasma concentrations of these factors are usually altered during infection and inflammation. However, they are not recommended as diagnostic markers for MAGIs [1478].

9.4.4.2.7 Reactive oxygen species

Reactive oxygen species may be increased in infertile patients with asymptomatic *C. trachomatis* and *M. hominis* infection, with subsequent decrease in ROS upon antibiotic treatment. However, the levels of ROS in infertile patients with asymptomatic *C. trachomatis* and *M. hominis* in the semen were low, making it difficult to draw any firm conclusions [1479]. Chronic urogenital infections are also associated with increased leukocyte numbers [1480]. However, their biological significance in prostatitis remains unclear [1448].

9.4.4.2.8 Disease management

Treatment of CP/CPPS is usually targeted at relieving symptoms [1481, 1482]. The indications and aims of therapy are:

- reduction or eradication of micro-organisms in prostatic secretions and semen;
- normalisation of inflammatory (e.g., leukocytes) and secretory parameters;
- improvement of sperm parameters associated with fertility impairment [1483].

Only antibiotic therapy of chronic bacterial prostatitis (NIH II according to the classification) has providedsymptomatic relief, eradication of micro-organisms, and a decrease in cellular and humoral inflammatory parameters in urogenital secretions. Although antibiotics might improve sperm quality [1483], there is no evidence that treatment of CP/CPPS increases the probability of natural conception [1448, 1484].

Asymptomatic presence of *C. trachomatis* and *M. hominis* in the semen can be correlated to impaired sperm quality, which recovers after antibiotic treatment. However further research is required to confirm these findings [1479].

9.4.4.3 Epididymitis

Inflammation of the epididymis causes unilateral pain and swelling, usually with acute onset. Among sexually active men < 35 years of age, epididymitis is most often caused by *C. trachomatis* or *N. gonorrhoea* [1485, 1486]. Sexually transmitted epididymitis is usually accompanied by urethritis. Non-sexually transmitted epididymitis is associated with urinary tract infection and occurs more often in men aged > 35 years [1487].

9.4.4.3.1 Diagnostic evaluation

9.4.4.3.1.1 Ejaculate analysis

Ejaculate analysis according to WHO Laboratory Manual for the Examination and Processing of Human Semen (5th edn) criteria, may indicate persistent inflammatory activity. Transient reductions in sperm counts and progressive motility can be observed [1485, 1488, 1489]. Semen culture might help to identify pathogenic micro-organisms. Development of stenosis of the epididymal ducts, reduction of sperm count, and azoospermia are more important potential sequelae to consider in the follow-up of bilateral epididymitis (see Chapter 9.3.2).

9.4.4.3.1.2 Disease management

Treatment of epididymitis results in:

- microbiological cure of infection;
- improvement of clinical signs and symptoms;
- prevention of potential testicular damage;
- prevention of transmission;
- decrease of potential complications (e.g., infertility or chronic pain).

Patients with epididymitis known or suspected to be caused by *N. gonorrhoeae* or *C. trachomatis* must be told to also refer their sexual partners for evaluation and treatment [1490].

9.4.4.4 Summary of evidence and recommendation for male accessory gland infections

Summary of evidence	**LE**
Male accessory gland infections are not clearly associated with impaired natural conception.	3
Antibiotic treatment often only eradicates micro-organisms; it has no positive effect on inflammatory alterations and cannot reverse functional deficits and anatomical abnormalities.	2a
Although antibiotic treatment for MAGIs may result in improvement in sperm quality, it does not enhance the probability of conception.	2a

Recommendations	**Strength rating**
Treating male accessory gland infections (MAGIs) may improve sperm quality, although it does not necessarily improve the probability of increasing conception.	Weak
Data is insufficient to conclude whether antibiotics and antioxidants for the treatment of infertile men with leukocytospermia may improve fertility outcomes.	Weak
Refer sexual partners of patients with accessory sex gland infections that are known or suspected to be caused by sexually transmitted diseases for evaluation and treatment.	Strong

9.5 Non-Invasive Male Infertility Management

*9.5.1 **Idiopathic male infertility and OATS***

Oligo-astheno-teratozoospermia (OAT) is a clinical condition, with a reduced number of spermatozoa in the ejaculate, which is also characterised by a reduced motility and morphology; often referred to as OAT syndrome (OATs). Several conditions can cause OATs, although the aetiology may be unknown in a significant number of cases [73, 1324].

*9.5.2 **Empirical treatments***

9.5.2.1 Life-style

Studies suggest that environmental and lifestyle factors may contribute to idiopathic infertility acting additively on a susceptible genetic background [73, 1324]. Hence, lifestyle improvement can have a positive effect on sperm parameters (see below).

9.5.2.1.1 Weight loss

Few authors have investigated the role of weight loss on male fertility outcomes. Non-controlled studies have suggested that weight loss can result in improved sperm parameters [73, 1491, 1492]. However, data derived from RCTs are more conflicting. In particular, a meta-analysis including a total of 28 cohort studies and 1,022 patients, documented that bariatric surgery had no effects in improving sperm quality and function in morbidly obese men [1493]. Data on ART outcomes are lacking. However, it is important to recognise that weight loss is able to improve obesity-related secondary hypogonadism which may result in better outcomes in couples seeking medical care for infertility and is important for the general health of the male partner [1491, 1493].

9.5.2.1.2 Physical activity

Regular physical activity is recommended by the WHO in order to prevent and reduced the risk of several long-term chronic diseases [1494]. A recent meta-analysis has documented that moderate-intensity (20-40 METs-h/week) or even high-intensity (40-80 METs-h/week) recreational physical activity can result in better semen parameters [1495]. In addition, similar to what is observed form weight loss improvements in hormonal profile have also been reported [1496].

9.5.2.1.3 Smoking

Epidemiological data has indicated that about one in three men of reproductive age smokes, with the highest prevalence observed in Europe among all the WHO regions [1497]. Data derived from a large meta-analysis including twenty studies and 5,865 participants has clearly documented a negative association between smoking and sperm parameters [1497]. Experimental studies performed in rats showed that nicotine has a dose-dependent deleterious effect on the sperm, which can be improved by nicotine cessation [1498]. Data in men are lacking and only one case report has indicated an improvement of sperm parameters after a three months smoking cessation program [1499]. Similar data have been reported in a recent non-controlled study, which showed a possible benefit on ART after the male partner stopped smoking [1500].

9.5.2.1.4 Alcohol consumption

Data derived from a recent meta-analysis including fifteen cross-sectional studies and 16,395 men suggested that moderate alcohol did not adversely affect semen parameters whereas higher alcohol intake can result in a detrimental effect on male fertility [1501]. Similar to what has been reported for weight loss, however, heavy chronic ethanol consumption (defined as > two drinks per day [1502]) can reduce testosterone levels which can be restored by alcohol cessation [1503].

9.5.2.2 Antioxidant treatment

Inflammation is a positive reaction of the human body to overcome potential noxious stimuli. However, chronic inflammation can induce several negative biochemical and metabolic effects contributing to the development of several medical conditions. Oxidative stress (OS) is considered one of the most important contributing factors in the pathogenesis of idiopathic infertility. ROS, the final products of OS, can impair sperm function acting at several levels including plasma membrane lipid peroxidation and which can affect sperm motility, the acrosome reaction and chromatin maturation leading to increased DNA fragmentation [1504]. Accordingly, seminal levels of ROS have been negatively associated with ART outcomes [1505]. Despite this, evidence for the role of antioxidant therapy in male patients with infertility is still conflicting. In a meta-analysis Cochrane Data Base Systemic Review including 34 RCTs and 2,876 couples using various antioxidant compounds, it was concluded that antioxidant therapy had a positive impact on live birth and pregnancy rates in sub-fertile couples undergoing ART cycles [1506]. Similar results were also reported in the most recent meta-analysis including 61 studies with a total population of 6,264 infertile men, aged between 18 and 65 year [1507]. However, all the aforementioned studies also recognised important limitations. In particular, data were derived

from low-quality RCTs with serious risk of bias due to poor methods of reporting randomisation, failure to report on the clinical outcomes including live birth rate and clinical pregnancy rate, high attrition rates, and also imprecision due to often low event rates and small overall sample sizes [1507]. In addition, no clear conclusion regarding the specific antioxidants to use or and/or therapeutic regimes for improving sperm parameters and pregnancy rate were possible [1507].

9.5.2.3 Selective oestrogen receptor modulators (SERMs)

Selective oestrogen receptor modulators (SERMs) have been advocated as a possible empiric treatment in male idiopathic infertility. The proposed mechanism of action is based on the activity of these compounds to block oestrogen receptors at the level of the hypothalamus, which results in stimulation of GnRH secretion leading to an increase in pituitary gonadotropin release. The latter effect, by stimulating spermatogenesis, represents the rational basis for SERM administration to patients with reduced sperm number [1508]. In an initial meta-analysis including eleven RCTs, in which only five were placebo-controlled, it was concluded that SERMs were not associated with an increased pregnancy rate in the 459 patients analysed [1509]. In a subsequent Cochrane review published one year later, these findings were confirmed, in a larger number of studies (n=10 and 738 men), although positive effects on hormonal parameters were documented. More recently, Chua *et al.* meta-analysed data derived from eleven RCTs showing that the use of SERM was associated with a statistically significant increased pregnancy rate [1510]. In addition, a significant improvement in sperm parameters and hormonal parameters were detected. Similar results were confirmed in the latest updated meta-analysis including sixteen studies [1508]. However, it should be recognised that the quality of the papers included is low and only a few studies are placebo-controlled. In conclusion, although some positive results relating to the use of SERMs in men with idiopathic infertility have been reported, no conclusive recommendations can be drawn due to poor quality of the available evidence. Furthermore, complications from the use of SERM are under reported.

9.5.2.4 Aromatase inhibitors

Aromatase, a cytochrome p450 enzyme, is present in the testes, prostate, brain, bone, and adipose tissue of men; it converts testosterone and androstenedione to estradiol and estrone, respectively. Estradiol negatively feeds back on the hypothalamus and pituitary to reduce gonadotropic secretions, ultimately affecting spermatogenesis. In this context, AIs may decrease oestrogen production by reversibly inhibiting cytochrome p450 isoenzymes 2A6 and 2C19 of the aromatase enzyme complex; inhibiting the negative feedback of oestrogen on the hypothalamus resulting in stronger GnRH pulses that stimulate the pituitary to increase production of FSH [1511-1514]. Aromatase activity has been associated with male infertility characterised by testicular dysfunction with low serum testosterone and/or testosterone to estradiol ratio. In this context, Aromatase inhibitors (AIs) have been reported to increase endogenous testosterone production and improve spermatogenesis in the setting of infertility as an off-label option for treatment [1515]. Either steroidal (testolactone) or non-steroidal (anastrozole and letrozole) AIs were found to statistically improve hormonal and semen parameters in infertile men, with a safe tolerability profile, although prospective RCTs are necessary to better define the efficacy of these medications in this clinical setting [1513, 1515].

Recommendations	Strength rating
In men with idiopathic oligo-astheno-teratozoospermia, life-style changes including weight loss and increased physical activity, smoking cessation and alcohol intake reduction can improve sperm quality and the chances of conception.	Weak
No clear recommendation can be made for treatment of patients with idiopathic infertility using antioxidants, although anti-oxidant use may improve semen parameters.	Weak
No conclusive recommendations on the use of selective oestrogen receptor modulators in men with idiopathic infertility can be drawn.	Weak
No conclusive recommendations on the use of either steroidal (testolactone) or non-steroidal (anastrozole and letrozole) aromatase inhibitors in men with idiopathic infertility can be drawn, even before testis surgery.	Weak

9.5.3 ***Hormonal therapy***

9.5.3.1 Gonadotrophins

Follicle Stimulating Hormone is primarily involved in the initiation of spermatogenesis and testicular growth during puberty. The role of FSH post puberty has not been clearly defined. Luteinising Hormone stimulates testosterone production in the testes, but due to its short half-life is not suitable for clinical use. Human Chorionic Gonadotrophin acts in a similar manner to LH and can be used pharmacologically to stimulate testosterone release in men with failure of their hypothalamic-pituitary axis. Human Chorionic Gonadotrophin

can adequately stimulate spermatogenesis in men whom have developed hypopituitarism after a normal puberty. Therefore, the treatment of men with secondary hypogonadism depends on whether or not they developed hypothalamic-pituitary failure before or after puberty [5].

9.5.3.2 Secondary Hypogonadism

(a) Pre-Pubertal-Onset

Congenital causes resulting in low gonadotropin production are associated with testicular size < 4 mL and/or cryptorchidism. Testes size of < 4 mL occurs when they have not been exposed to any gonadotropins at all. These conditions require combination therapy with both hCG and FSH with subcutaneous administration or GnRH by pulsed delivery using a subcutaneous pump [1516]. However, GnRH treatment requires a pulsatile secretion using specific devices for either intravenous or subcutaneous administration, which may limit patient compliance. Moreover, GnRH therapy should be limited to subjects with a residual pituitary gonadotropic activity [5].

As for the type of gonadotropin treatment, it is usual to commence hCG first and titrate the dose to achieve testosterone levels within the normal physiological range. However, FSH can be given first or in combination with hCG [105]. Human Chorionic Gonadotrophin is given twice weekly and in patients with congenital secondary hypogonadism in high dose, commencing at 1,000 IU twice weekly. Testosterone levels can be assayed every two weeks with dosage increases until ideally mid-range testosterone is achieved. Dose increases can be to 2,000 IU, 3,000 IU, 4,000 IU and 5,000 IU all two to three times a week, until normal testosterone levels are achieved [1517-1520]. Failure to achieve normal testosterone status at the high dose would indicate that primary testicular failure is present, probably as a result of cryptorchidism or failure of testicular development. Human Chorionic Gonadotrophin is also used to stimulate testicular descent into the scrotum in subjects with cryptorchidism. Once the hCG dose giving a normal level testosterone is established with the implication that intra-testicular testosterone has occurred FSH 75-150 IU three times per week subcutaneously should be commenced. Usually the higher 150 IU dose three times weekly is needed to be successful in men with testes size < 4mL. The trophic response of the testes to FSH is variable in these patients and it may range from no effect to achieving testicular sizes of 12-15 mL [1521]. A trophic response is usually an indication of an increase in spermatogenesis. The production of new spermatogenesis may be evident after three months of FSH therapy, but could occur even up to eighteen months of treatment [1519-1521]. A low baseline sperm concentration does not indicate a poor response to gonadotropin therapy [1522]. Semen analysis can be assessed at three monthly intervals. These patients can be fertile with low sperm counts much less than 20 million/mL as there is a high proportion of motile sperm. Follicle-stimulating hormone SH therapy prior to GnRH is also effective in stimulating testicular growth and fertility in men with congenital hypogonadotrophic hypogonadism [1523]. A larger initial testicular volume is the best prognostic factor for induction of successful spermatogenesis [1524].

(b) Post-Pubertal Onset Secondary

If secondary hypogonadism develops after puberty, hCG alone is usually required first to stimulate spermatogenesis. Doses of subcutaneous hCG required may be lower than those used in individuals with pre-pubertal onset; therefore, a starting dose of 250 IU twice weekly is suggested, and if normal testosterone levels are reached, hCG doses may be increased up to 2,000 IU twice weekly as per pre-pubertal onset above. Again, semen analysis should be performed every three months to assess response, unless conception has taken place. If there is a failure of stimulation of spermatogenesis, then FSH can be added (75 IU three times per week, increasing to 150 IU three times per week if indicated). Similarly, a combination therapy with FSH and hCG can be administered from the beginning of treatment, promoting better outcomes in men with secondary hypogonadism [105]. No difference in outcomes have been observed when urinary-derived, highly purified FSH was compared to recombinant FSH [105].

Greater baseline testicular volume is a good prognostic indicator for response to gonadotrophin treatment [1524]. Data had suggested that previous testosterone therapy could negatively impact on gonadotropins treatment outcomes in men with secondary hypogonadism [1524]. However, this observation had been subsequently refuted by a meta-analysis which did not confirm a real negative role of testosterone therapy in terms of future fertility in this specific setting of men [105].

In the presence of hyperprolactinaemia, causing suppression of gonadotrophins resulting in sub-fertility the treatment independent of aetiology (including a pituitary adenoma) is dopamine agonist therapy or withdrawal of a drug which causes the condition. Dopamine agonists used include bromocritpine, cabergoline and quinagolide.

9.5.3.3 Primary Hypogonadism

There is no substantial evidence that gonadotrophin therapy has any beneficial effect in the presence of classical testicular failure. Likewise, there is no data to support the use of other hormonal treatments (including SERMs or AIs) in the case of primary hypogonadism to improve spermatogenesis [74, 1525].

9.5.3.4 Idiopathic Male Factor Infertility

There is some evidence that FSH treatment increases sperm parameters in idiopathic oligozoospermic men with FSH levels within the normal range (generally 1.5 - 8 mIU/mL). It has also been reported that FSH may improve sperm DNA fragmentation rates as well as ameliorating AMH and inhibin levels [1526-1529]. High-dose FSH therapy is more effective in achieving a testicular response than lower doses. A Cochrane Database Systemic Review including six RCTs with 456 participants, different treatment protocols and follow-up periods concluded that FSH treatment resulted in higher live birth and pregnancy rates compared to either placebo or no treatment. However, no significant difference among groups was observed when ICSI or IUI were considered [1530]. In a more recent meta-analysis including fifteen trials with more than 1,200 patients, similar findings after FSH treatment were observed in terms of both spontaneous pregnancies and pregnancies after ART [1531]. A further study showed that in azoospermic men undergoing TESE-ICSI there were improved sperm retrieval rates and higher pregnancy and fertilisation rates in men treated with FSH compared to non-treated subjects [1532]. In men with NOA, the combination of hCG/FSH therapy has in only one study been shown to increase sperm retrieval rates [1533]. Human Chorionic Gonadotrophin alone prior to TESE in NOA has not been found to have any benefit on sperm retrieval rates [1534].

9.5.3.5 Anabolic Steroid Abuse

Oligospermia or azoospermia as a result of anabolic abuse should be treated initially by withdrawal of the anabolic steroid. There is no common indication for treating this disorder; the management is based on case reports and clinical experience. Usually, adequate sperm numbers and quality will improve over a six to twelve month period. If after this interval the condition persists, then hCG without or in combination with FSH as an alternative to clomiphene can be used to try and stimulate spermatogenesis [1535].

9.5.3.6 Recommendations for treatment of male infertility with hormonal therapy

Recommendations	Strength rating
Hypogonadotropic hypogonadism (secondary hypogonadism), including congenital causes, should be treated with combined human chorionic gonadotropin (hCG) and follicle-stimulating hormone (FSH) (recombinant FSH; highly purified FSH) or pulsed Gonadotropin-releasing hormone (GnRH) via pump therapy to stimulate spermatogenesis.	Strong
In men with hypogonadotropic hypogonadism, induce spermatogenesis by an effective drug therapy (hCG; human menopausal gonadotropins; recombinant FSH; highly purified FSH).	Strong
The use of GnRH therapy is more expensive and does not offer any advantages when compared to gonadotropins for the treatment of hypogonadotropic hypogonadism.	Strong
In men with idiopathic oligozoospermia and FSH values within the normal range, FSH treatment may ameliorate spermatogenesis outcomes.	Weak
No conclusive recommendations can be given on the use of high dose FSH in men with idiopathic infertility prior (m)TESE and therefore cannot be routinely advocated.	Weak
Do not use testosterone therapy for the treatment of male infertility.	Strong
Provide testosterone therapy for symptomatic patients with primary and secondary hypogonadism who are not considering parenthood.	Strong
In the presence of hyperprolactinaemia dopamine agonist therapy may improve spermatogenesis.	Weak

9.6 Invasive Male Infertility Management

*9.6.1 **Obstructive azoospermia***

Obstructive azoospermia is the absence of spermatozoa in the sediment of a centrifuged sample of ejaculate due to obstruction [1536]. Obstructive azoospermia is less common than NOA and occurs in 20-40% of men with azoospermia [1537, 1538]. Men with OA usually have a normal FSH, testes of normal size and epididymal enlargement [1539]. Of clinical relevance, men with late maturation arrest may present with normal gonadotrophins and testis size and may be only be distinguished from OA at the time of surgical exploration.

The vas deferens may be absent bilaterally (CBAVD) or unilaterally (CUAVD). Obstruction in primary infertile men is more frequently present at the epididymal level.

9.6.1.1 Classification of obstructive azoospermia

9.6.1.1.1 Intratesticular obstruction

Intratesticular obstruction occurs in 15% of men with OA [1540]. Congenital forms are less common than acquired forms (post-inflammatory or post-traumatic) (Table 35).

9.6.1.1.2 Epididymal obstruction

Epididymal obstruction is the most common cause of OA, affecting 30-67% of azoospermic men [1540-1543]. Congenital epididymal obstruction usually manifests as CBAVD, which is associated with at least one mutation of the CF gene in 82% of cases [1543]. Other congenital forms of epididymal obstruction include chronic sinu-pulmonary infections (Young's syndrome) [1544]. Acquired forms secondary to acute (e.g., gonococcal) and subclinical (e.g., chlamydial) epididymitis are most commonly due to infections [1545, 1546]. Other causes may be trauma or surgical intervention (Table 35) [1547, 1548].

9.6.1.1.3 Vas deferens obstruction

Vas deferens obstruction is the most common cause of acquired obstruction following vasectomy (Table 35) [1545]. Approximately 2-6 % of these men request vasectomy reversal (see section from EAU Guidelines on Male Infertility 2019 for this topic). Vasal obstruction may also occur after hernia repair [1549, 1550]. The most common congenital vasal obstruction is CBAVD, often accompanied by CF. Unilateral agenesis or a partial defect is associated with contralateral seminal duct anomalies or renal agenesis in 80% and 26% of cases, respectively [1245].

9.6.1.1.4 Ejaculatory duct obstruction

Ejaculatory duct obstruction is found in 1-5% of cases of OA and is classified as either cystic or post-inflammatory or calculi of one or both ejaculatory ducts (Table 35) [1380, 1551]. Cystic obstructions are usually congenital (i.e., Mullerian duct cyst or urogenital sinus/ejaculatory duct cysts) and are typically midline. In urogenital sinus abnormalities, one or both ejaculatory ducts empty into the cyst [1552], while in Mullerian duct anomalies, the ejaculatory ducts are laterally displaced and compressed by the cyst [1553]. Paramedian or lateral intraprostatic cysts are rare [1554]. Post-inflammatory obstructions of the ejaculatory duct are usually secondary to urethroprostatitis [1555]. Congenital or acquired complete obstructions of the ejaculatory ducts are commonly associated with low semen volume, decreased or absent seminal fructose, and acidic pH. The seminal vesicles (anterior-posterior diameter > 15 mm) and ejaculatory duct (> 2.3 mm in width) are usually dilated [1551, 1555-1557].

9.6.1.1.4.1 Functional obstruction of the distal seminal ducts

Functional obstruction of the distal seminal ducts might be attributed to local neurogenic dysfunction [1558]. This abnormality is often associated with urodynamic dysfunction. Impaired sperm transport can be observed as idiopathic or due to spinal cord injury, multiple sclerosis, retroperitoneal lymph node dissection, pelvic surgery and selective serotonin re-uptake inhibitors (SSRI), α-blockers and typical antipsychotic medication [1559].

Traumatic
Postsurgical iatrogenic obstruction
Functional obstruction
Idiopathic/acquired local neurogenic dysfunction

9.6.1.2 Diagnostic evaluation

9.6.1.2.1 Clinical history

Clinical history taking should follow the investigation and diagnostic evaluation of infertile men (See section 10.3). Risk factors for obstruction include prior surgery, iatrogenic injury during inguinal herniorrhaphy, orchidopexy or hydrocelectomy.

9.6.1.2.2 Clinical examination

Clinical examination should follow the guidelines for the diagnostic evaluation of infertile men. Obstructive azoospermia is indicated by at least one testis with a volume > 15 mL, although a smaller volume may be found in some patients with:

- Obstructive azoospermia and concomitant partial testicular failure;
- enlarged and dilated epididymis;
- nodules in the epididymis or vas deferens;
- absence or partial atresia of the vas.

9.6.1.2.3 Semen analysis

Azoospermia means the inability to detect spermatozoa after centrifugation at ×400 magnification. At least two semen analyses must be carried out [1536, 1560] (see section 10.3). When semen volume is low, a search must be made for spermatozoa in urine after ejaculation. Absence of spermatozoa and immature germ cells in the semen pellet suggest complete seminal duct obstruction.

9.6.1.2.4 Hormone levels

Hormones including FSH and inhibin-B should be normal, but do not exclude other causes of testicular azoospermia (e.g., NOA). Although inhibin-B concentration is a good index of Sertoli cell integrity reflecting closely the state of spermatogenesis, its diagnostic value is no better than that of FSH and its use in clinical practice has not been widely advocated [1561].

9.6.1.2.5 Genetic Testing

Inability to palpate the vas on one or both sides should raise concern for a CFTR mutation. Any patient with unilateral or bilateral absence of the vas deferens or seminal vesicle agenesis should be offered CFTR testing [1562].

9.6.1.2.6 Testicular biopsy

Testicular biopsy must be combined with TESE for cryopreservation. Although studies suggest that a diagnostic or isolated testis biopsy [1563] is the most important prognostic predictor of spermatogenesis and sperm retrieval, the panel recommends not to perform testis biopsies (including fine needle aspiration [FNA]) without performing simultaneously a therapeutic sperm retrieval, as this will require a further invasive procedure after biopsy. Furthermore, even patients with extremes of spermatogenic failure (e.g., Sertoli Cell Only syndrome [SCOS]) may harbour focal areas of spermatogenesis [1564, 1565].

9.6.1.3 Disease management

Sperm retrieval

9.6.1.3.1 Intratesticular obstruction

Only TESE allows sperm retrieval in these patients and is therefore recommended.

9.6.1.3.2 Epididymal obstruction

Microsurgical epididymal sperm aspiration (MESA) or percutaneous epididymal sperm aspiration (PESA) [1566] is indicated in men with CBAVD. Testicular sperm extraction (TESE) and percutaneous techniques, such as testicular sperm aspiration (TESA), are also options [1567]. The source of sperm used for ICSI in cases of OA and the aetiology of the obstruction does not affect the outcome in terms of fertilisation, pregnancy, or miscarriage rates [1568]. Usually, one MESA procedure provides sufficient material for several ICSI cycles [1569] and it produces high pregnancy and fertilisation rates [1570]. In patients with OA due to acquired epididymal obstruction and with a female partner with good ovarian reserve, microsurgical epididymovasostomy (EV) is recommended [1571]. Epididymovasostomy can be performed with different techniques such as end-to-site and intussusception [1572].

Anatomical recanalisation following surgery may require 3 to 18 months. A recent systematic review indicated that the time to patency in EV varies between 2.8 to 6.6 months. Reports of late failure are heterogenous and vary between 1-50% [1573]. Before microsurgery, and in all cases where recanalisation is impossible, epididymal spermatozoa should be aspirated intra-operatively by MESA and cryopreserved to be used for subsequent ICSI procedures [1555]. Patency rates range between 65% and 85% and cumulative pregnancy rates between 21% and 44% [1548, 1574]. Recanalisation success rates may be adversely affected by pre-operative and intra-operative findings. Robot-assisted EV has similar success rates and larger studies are needed [1431].

9.6.1.3.3 Vas deferens obstruction after vasectomy

Vas deferens obstruction after vasectomy requires microsurgical vasectomy reversal. The mean post-procedure patency and pregnancy rates weighted by sample size were 90-97% and 52-73%, respectively [1548, 1574]. The average time to patency is 1.7 to 4.3 months and late failures are uncommon (0-12%) [1573]. Robot-assisted vasovasostomy has similar success rates and larger studies are needed to establish its benefits over standard microsurgical procedures including cost-benefit analysis [1431].

The absence of spermatozoa in the intra-operative vas deferens fluid suggests the presence of a secondary epididymal obstruction, especially if the seminal fluid of the proximal vas has a thick “toothpaste” appearance; in this case microsurgical EV may be indicated [1575-1577]. A simultaneous sperm retrieval may be performed for future cryopreservation and use for ICSI; likewise, patients should be counselled appropriately.

9.6.1.3.4 Vas deferens obstruction at the inguinal level

It is usually impossible to correct large bilateral vas deferens defects, resulting from involuntary excision of the vasa deferentia during hernia surgery in early childhood or previous orchidopexy. In these cases, TESE/MESA/PESA or proximal vas deferens sperm aspiration [1578] can be used for cryopreservation for future ICSI. Prostate cancer patients who express an interest in future fertility should be counselled for cryopreservation [1579].

9.6.1.3.5 Ejaculatory duct obstruction

The treatment of ejaculatory duct obstruction depends on its aetiology. Transurethral resection of the ejaculatory ducts (TURED) can be used in post-inflammatory obstruction and cystic obstruction [1551, 1555]. Resection may remove part of the verumontanum. In cases of obstruction due to a midline intraprostatic cyst, incision, unroofing or aspiration of the cyst is required [1551, 1555].

Intra-operative TRUS makes this procedure safer. If distal seminal tract evaluation is carried out at the time of the procedure, installation of methylene blue dye into the seminal vesicles (chromotubation) can help to confirm intra-operative opening of the ducts. Pregnancy rates after TURED are approximately 20-25% [1380, 1551, 1580]. Complications following TURED include epididymitis, urinary tract infection, gross haematuria, haematospermia, azoospermia (in cases with partial distal ejaculatory duct obstruction) and urine reflux into the ejaculatory ducts and seminal vesicles [1551].

Alternative therapies for EDO include, seminal vesiculoscopy to remove debris or calculi and balloon dilation and laser incision for calcification on TRUS [1581]. The alternatives to TURED are MESA, PESA, TESE, proximal vas deferens sperm aspiration and seminal vesicle-ultrasonically guided aspiration.

9.6.1.4 Summary of evidence and recommendations for obstructive azoospermia

Summary of evidence	**LE**
Obstructive lesions of the seminal tract are frequent in azoospermic or severely oligozoospermic patients, usually with normal-sized testes and normal reproductive hormones.	3

Recommendations	**Strength rating**
Perform microsurgical vasovasostomy or epididymovasostomy for azoospermia caused by epididymal or vasal obstruction in men with female partners of good ovarian reserve.	Strong
Use sperm retrieval techniques, such as microsurgical epididymal sperm aspiration (MESA), testicular sperm extraction (TESE) and percutaneous techniques (PESA, TESA) either as an adjunct to reconstructive surgery, or if the condition is not amenable to surgical repair, or when the ovarian reserve of the partner is limited or patient preference is not to undertake a surgical reconstruction and the couple prefer to proceed to ICSI treatment directly.	Strong

9.6.2 ***Non-obstructive azoospermia***

Non-obstructive azoospermia (NOA) is defined as the absence of sperm at the semen analysis after centrifugation, with usually a normal ejaculate volume. This finding should be confirmed at least at two consecutives semen analyses [1582]. The severe deficit in spermatogenesis observed in NOA patients is often a consequence of primary testicular dysfunction or may be related to a dysfunction of the hypothalamus-pituitary-gonadal (HPG) axis.

9.6.2.1 Investigation of Non-obstructive azoospermia

The diagnosis of NOA is based on the evidence of two consecutive semen analyses confirming azoospermia. Moreover, causes of OA should be ruled out. Patients with NOA should undergo a comprehensive assessment aimed to identify genetically transmissible conditions, potential treatable causes of azoospermia, and potential health-relevant comorbidities (e.g., testis cancer and hypogonadism [any type]). A detailed medical history (e.g., history of cryptorchidism, previous gonadotoxic treatments for cancer), also including socio-demographic characteristics [1583], along with a comprehensive physical examination should be performed in every patient to detect conditions potentially leading to azoospermia, while ruling out comorbidities frequently associated with azoospermia. Indeed, NOA could be the first sign of pituitary tumours or germ cell tumours of the testis [1584-1586]. Patients with NOA have been shown to be also at increased risk of being further diagnosed with cancer [1587]. Moreover, other systemic conditions such as metabolic syndrome, type 2 diabetes, osteoporosis and cardiovascular diseases (CVDs) have been more frequently observed in patients with NOA compared to normozoospermic men [1588-1590]. Therefore investigation of the infertile male provides an opportunity for long-term risk stratification for other co-morbid conditions [1591].

Genetic tests should be performed in patients with NOA to detect genetic abnormalities. As discussed (see section 10.3), patients should undergo karyotype analysis [1208, 1209], along with a screening of Y-chromosome microdeletions [1259, 1592] and of the gene coding for CFTR in order to exclude concomitant mutations, and to rule out CBAVD [1240, 1241]. Genetic counselling for eventual transmissible and health-relevant genetic conditions should be provided to couples.

As detailed, all patients should undergo a complete hormonal investigation to exclude a concomitant hypogonadism, which has been found in about 30% of patients with NOA [341, 1593, 1594]. A correct definition of the type of the associated hypogonadism (i.e., hypogonadotropic hypogonadism versus hypergonadotropic vs. compensated hypogonadism) is fundamental to differentiate diagnostic and therapeutic approaches to the patient [1595].

Scrotal US may show signs of testicular dysgenesis (e.g., non-homogeneous testicular architecture and/or microcalcifications) and testis tumours. Testicular volume may be a predictor of spermatogenic function [1186] and is usually, but not invariably, low in patients with NOA. Some authors advocated that testicular perfusion detected at US Doppler assessment can predict surgical sperm retrieval at TESE and guide testicular biopsies [1596]; however, to date data are inconsistent to suggest a routine role of testis Doppler evaluation before TESE.

9.6.2.2 Surgery for non-obstructive azoospermia

Surgical treatment for NOA is mostly aimed to retrieve vital sperm directly from the testis (either uni- or bilaterally). This treatment is normally part of assisted reproductive technology (ART) protocols, including IVF cycles via intracytoplasmic sperm injection (ICSI). Techniques and indications for surgical sperm retrieval in patients with NOA are discussed below. As detailed, any surgical approach aimed at sperm retrieval must be considered not a routine and simple biopsy; in this context, performing a diagnostic biopsy before surgery (any type) unless dedicated to ART protocols is currently considered inappropriate.

9.6.2.3 Indications and techniques of sperm retrieval

Spermatogenesis within the testis may be focal, which means that spermatozoa can usually be found in small and isolated foci. With a wide variability among cohorts and techniques, positive sperm retrieval rates have been reported in up to 50% of patients with NOA [1597, 1598]. Numerous predictive factors for positive sperm retrieval have been investigated, although no definitive factors have been demonstrated to predict sperm retrieval [1598].

Historically, there is a good correlation between the histology found at testicular biopsy and the likelihood of finding mature sperm cells during testicular sperm retrieval [1563, 1599, 1600]. The presence of hypospermatogenesis at testicular biopsy showed a good accuracy in predicting positive sperm retrieval after either single or multiple conventional TESE or mTESE compared to maturation arrest pattern or a SCOS [1563, 1599, 1600]. However, a diagnostic biopsy is not recommended in this clinical setting for the reasons outlined above.

Hormonal levels, including FSH, LH, inhibin B and AMH have been variably correlated with sperm retrieval outcomes at surgery, and data from retrospective series are still controversial [1601-1607]. Similarly, conflicting results have been published regarding testicular volume as a predictor of positive sperm retrieval [1563, 1604, 1605]. Therefore, no clinical variable may be currently considered as a reliable predictor for positive sperm retrieval throughout ART patient work-up [1598].

In case of complete AZFa and AZFb microdeletions, the likelihood of sperm retrieval is zero and therefore TESE procedures are contraindicated [1258]. Conversely, patients with Klinefelter syndrome [1225] and a history of undescended testes have been shown to have higher chance of finding sperm at surgery [1604].

Historically, surgical techniques for retrieving sperm in men with NOA include testicular sperm aspiration (TESA), single or multiple conventional TESE (cTESE) and mTESE.

Fine needle aspiration (FNA)

Fine needle aspiration (FNA) mapping technique has been proposed as a prognostic procedure aimed to select patients with NOA for TESE and ICSI [1608]. The procedure is performed under local anaesthesia in the office and percutaneous aspiration is performed with 23G needle in multiple sites, ranging from 4 to 18 [1608]. The retrieved tissue is sent for cytological and histological evaluation in order to provide information on the presence of mature sperm and on testicular histological pattern. Moreover, given that focal spermatogenesis may occur within the testis of patients with NOA, FNA mapping may provide information on the sites with the higher probability of retrieving sperms, thus serving as a guide for further sperm retrieval surgery in the context of ART procedures (e.g., ICSI). Turek *et al.* have shown that a higher number of aspiration sites may increase the chance of finding sperm [1609, 1610]. The extent and type of subsequent sperm retrieval procedure can be tailored according to the FNA mapping results: TESA or TESE could be suggested in case of multiple positive sites for sperm, while a more precise and potentially more invasive technique, such as mTESE, could be considered for patients with only few positive sites at FNA [1608]. However, there are no RCTs comparing the diagnostic yield from FNA vs. mTESE. Furthermore, a positive FNA will require a secondary therapeutic surgical approach, which may increase the risk of testis damage and without appropriate cost-benefit analysis is not justifiable. Furthermore, there are no studies evaluating the salvage rate of mTESE in men who have undergone FNA mapping. Therefore, FNA mapping cannot be recommended as a primary therapeutic intervention in men with NOA until further RCTs are undertaken.

Testicular sperm aspiration

Testicular sperm aspiration (TESA) is a minimally invasive, office-based, procedure in which testicular tissue is retrieved with a biopsy needle under local anaesthesia. Reported sperm retrieval rates with TESA range from 11 to 60% according to patients' profile and surgical techniques [1611-1614]. Data have shown that using larger needles with (18-21G) with multiple passes could yield a higher chance of positive sperm retrieval [1614]. Complications after TESA are very uncommon and mainly include minor bleeding with scrotal haematoma and post-operative pain [1614].

As a less invasive and less-costly procedure TESA has been proposed as a possible first-line approach before sending patients to a more invasive procedure [1614]. To date there are no RCTs comparing sperm retrieval rates from TESA, cTESE or mTESE. A recent meta-analysis including data from case-control studies, reported that TESE was two times (95% CI 1.8-2.2) more likely to result in successful sperm retrieval as compared with TESA [1598]. Given the low success rates compared to TESE, TESA is no longer recommended in men with NOA.

Conventional TESE

Conventional TESE (cTESE) requires a scrotal incision and an open biopsy of the testis. Reported sperm retrieval rates in single-arm studies are about 50% [1597]. However, pooled data analysis of case-control studies comparing conventional TESE with mTESE showed a lower unadjusted sperm retrieval rate of 35% (95% CI 30-40) for cTESE [1598]. Observational studies have demonstrated that multiple biopsies yield a higher chance of sperm retrieval [1597, 1615].

The probability of finding vital sperm at TESE varies also according to testicular histology: data from non-randomised studies comparing cTESE with mTESE have shown a higher chance of sperm retrieval with mTESE only for patients with an histological finding of SCOS [1616]: in such cases results ranged from 22.5 to 41% and from 6.3 to 29% for mTESE versus cTESE, respectively [1616]. Conversely, no difference between the two techniques has been found when comparing patients with a histology suggestive for maturation arrest [1616]. A single study showed a small advantage of mTESE when hypospermatogenesis was found [1617]. In light of these findings some authors have advocated that cTESE could be the technique of choice in patients with a histological finding of maturation arrest or hypospermatogenesis [1598, 1616].

Conventional TESE has been associated with a higher rate of complications compared to other techniques [1597]. A total of 51.7% of patients have been found with intratesticular haematoma at scrotal US three months after surgery, with testicular fibrosis observed in up to 30% of patients at 6-month assessment [1618].

A recent meta-analysis has investigated the risk of hypogonadism after TESE due to testicular atrophy [1619]; patients with NOA experienced a mean 2.7 nmol/L decrease in total testosterone 6 months after cTESE, which recovered to baseline in a time frame between 18 and 26 months.

Microdissection TESE)

Microdissection TESE (mTESE) is aimed at identifying sites of focal spermatogenesis within the testis by performing focal biopsies in areas where larger dilated (and opaque) tubules are present by using optical magnification (20-25x) [1620]. The rationale of this technique is to increase the probability of retrieving sperm with a lower amount of sampled tissue and a consequent lower risk of complications.

Unadjusted sperm retrieval rate after mTESE was 52% (95% CI 47-58) in a pooled data analysis of studies comparing cTESE with mTESE [1598]. Specifically, mTESE resulted in a 1.5 higher chance of retrieving sperm compared to the conventional technique [1598]. In a study assessing the role of salvage mTESE after a previously failed cTESE or TESA, sperm were successfully retrieved in 46.5% of cases [1565]. Lower rates of complications have been observed with mTESE as compared to cTESE, both in terms of haematoma and fibrosis [1616]. Both procedures have shown a recovery of baseline testosterone levels at long-term follow-up [1617].

A recent meta-analysis of the currently available studies comparing cTESE vs. mTESE in patients with NOA showed a mean sperm retrieval rate of 47% (95% CI 45;49). No differences were observed when mTESE was compared to cTESE (46[range 43;49]% for cTESE versus 46[range 42;49]% for mTESE, respectively). Meta-regression analysis demonstrated that SRR per cycle was independent of age and hormonal parameters at enrolment. However, the SRR increased as a function of testis volume. Retrieved sperms resulted in a live birth rate of up to 28% per ICSI cycle [1621].

Although no difference between cTESE/mTESE techniques in subjects with NOA was found, to conclusively clarify if one technique is superior to the other, there is a need for a sufficiently powered and well-designed RCTs to compare mTESE to cTESE; therefore, a clear recommendation regarding the technique of choice cannot be given. Several variables should be considered before counselling patients for one specific technique including surgical skills, testicular histology, costs of the procedure and risk of complications.

Follow-up after TESE

When compared with cTESE, mTESE has been reported to have fewer post-operative complications and negative effects on testicular function. In a recent meta-analysis analysing the complications of TESE, men with Klinefelter syndrome and NOA had the largest decrease in total testosterone levels 6 months after TESE (mean decrease of 4.1 and 2.7 nmol/l) respectively, which recovered to baseline levels 26 and 18 months after TESE, respectively [1619]. Therefore, it would be reasonable to provide long-term endocrinological follow-up after TESE (any type) to detect hypogonadism, particularly for patients with Klinefelter syndrome; testosterone levels assessment could be offered in asymptomatic men at 18 months post TESE or in those men who become symptomatic for hypogonadism after surgery [1622].

Hormonal therapy prior to surgical sperm retrieval approaches

Stimulating spermatogenesis by optimising intratesticular testosterone (ITT) has been proposed to increase the chance of sperm retrieval at the time of surgery in men with NOA. Similarly, increasing FSH serum levels could stimulate spermatogenesis. There is evidence that treatment with hCG can lead to an increase in ITT [1528] and Leydig cells within the testis [1623]. Moreover, it has been shown that in azoospermic patients with elevated gonadotropins levels, administration of HCG and/or FSH can lead to a so-called “gonadotropins reset”, with a reduction in FSH plasma concentrations and an improvement in Sertoli cells function [1624]. Similarly, clomiphene citrate may increase pituitary secretion by blocking feedback inhibition of estradiol, thus inducing an increase in FSH and LH in patients with NOA [1625]. Overall, whilst azoospermic patients with secondary hypogonadism should be treated accordingly to stimulate sperm production [341], there is currently no RCT showing a benefit of hormonal treatment to enhance the chances of sperm retrieval among patients with idiopathic NOA. In a large multicentre case-control study, 496 patients with idiopathic NOA treated with a combination of clomiphene, HCG and human menopausal gonadotropin according to hormonal profile, were compared to 116 controls subjected to mTESE without receiving any pre-operative treatment [1533]. A total of 11% of treated patients had sperm in the ejaculate at the end of treatment; of the remaining patients, 57% had positive sperm retrieval at mTESE as compared with 33% in the control group. Likewise, a small case-control study including 50 men with idiopathic NOA, of whom 25 were treated with recombinant FSH before mTESE,

the authors observed a 24% sperm retrieval rate compared to 12% in the control group [1532]. Conversely, Gul *et al.* [1626] failed to find any advantage of pre-operative treatment with HCG compared to no treatment, in 34 idiopathic NOA patients candidates for mTESE.

Moreover, hormonal therapy has been proposed to increase the chance of sperm retrieval at salvage surgery after a previous failed cTESE or mTESE. Retrospective data have shown that treatment with HCG and recombinant FSH could lead to a 10-15% sperm retrieval rate at salvage mTESE [1528, 1627]. In a small case-control study 28 NOA patients were treated with HCG with or without FSH for 4-5 months before salvage mTESE and compared with 20 controls subjected to salvage surgery [1628]. Sperm retrieval rate was 21% in the treated group compared to 0% in the control group. The histological finding of hypospermatogenesis emerged as predictor of sperm retrieval at salvage surgery after hormonal treatment [1628]. Further prospective trials are needed to elucidate the effect of hormonal treatment before salvage surgery in NOA patients, with a previously failed cTESE or mTESE. However, patients should be counselled that the evidence for the role of hormone stimulation prior to sperm retrieval surgery in men with idiopathic NOA is limited [1629]. Currently, it is not recommended in routine practice.

9.6.2.4 Recommendations for Non-Obstructive Azoospermia

Recommendations	Strength rating
Patients with non-obstructive azoospermia should undergo a comprehensive assessment, including detailed medical history, hormonal profile and genetic tests to investigate the underlying aetiology and associated comorbidities. Genetic counselling is mandatory in couples with genetic abnormalities prior to any assisted reproductive technology protocols.	Strong
Surgery for sperm retrieval can be performed in men who are candidates for ART (i.e., ICSI). In patients with complete AZFa and AZFb microdeletions surgery is contraindicated since the chance of sperm retrieval is zero.	Strong
Fine needle aspiration (FNA) and testicular sperm aspiration (TESA) should not be considered the treatments of choice in patients with NOA, given the lower probability of positive sperm retrieval compared to cTESE and mTESE.	Weak
Fine needle aspiration as a prognostic procedure prior to definitive testicular sperm extraction (any type) in patients with NOA is not recommended for use in routine clinical practice.	Weak
Conventional TESE (cTESE) or microdissection TESE (mTESE) are the techniques of choice for retrieving sperm in patients with NOA.	Weak
No pre-operative biochemical and clinical variables may be considered sufficient and reliable predictors of positive sperm retrieval at surgery in patients with NOA.	Weak
No conclusive recommendations on the routine use of medical therapy (e.g., recombinant follicle-stimulating hormone (FSH); highly purified FSH; human chorionic gonadotrophin (hCG); aromatase inhibitors or selective oestrogen receptor modulators [SERMs]) in patients with NOA can be drawn and are not therefore currently recommended routinely before TESE.	Weak

9.7 Assisted Reproductive Technologies

*9.7.1 **Types***

Assisted reproductive technology consists of procedures that involve the *in vitro* handling of both human oocytes and sperm, or of embryos, with the objective of establishing a pregnancy [1630].

Once couples have been prepared for treatment, the following are the steps that make up an ART cycle:

1. Pharmacological stimulation of growth of multiple ovarian follicles, while at the same time other medications are given to suppress the natural menstrual cycle and down-regulate the pituitary gland.
2. Careful monitoring at intervals to assess the growth of the follicles.
3. Ovulation triggering: when the follicles have reached an appropriate size, a drug is administered to bring about final maturation of the eggs.
4. Egg collection (usually with a trans-vaginal US probe to guide the pickup) and, in some cases of male infertility, sperm retrieval.
5. Fertilisation process, which is usually completed by IVF or ICSI.
6. Laboratory procedures follow for embryo culture: culture media, oxygen concentration, co-culture, assisted hatching etc.
7. The embryos are then placed into the uterus. Issues of importance here include endometrial preparation, the best timing for embryo transfer, how many embryos to transfer, what type of catheter to use, the use of US guidance, need for bed rest etc.
8. Then there is luteal phase support, for which several hormonal options are available.

Fertility treatments are complex and each cycle consists of several steps. If one of the steps is incorrectly applied, conception may not occur [1630].

Several ART techniques are available:

9.7.1.1 Intra-uterine insemination (IUI): IUI is an infertility treatment that involves the placement of the prepared sperm into the uterine cavity timed around ovulation. This can be done in combination with ovarian stimulation or in a natural cycle. The aim of the stimulated cycle is to increase the number of follicles available for fertilisation and to enhance the accurate timing of insemination in comparison to the natural cycle IUI [1631-1633].

Intra-uterine insemination is generally, though not exclusively, used when there is at least one patent fallopian tube with normal sperm parameters and regular ovulatory cycles (unstimulated cycles) and when the female partner is less than 40 years of age.

The global pregnancy rate (PR) and delivery rate (DR) per IUI cycles with husband sperm are 12.0% and 8.0%, respectively. Using donor sperm the resultant PR and DR per cycle are 17.0% and 12.3%, respectively [1634]. The rates of successful treatment cycles for patients decrease with the increase in age, and the birth rates across all age groups have remained broadly stable over time. The highest birth rates were reported in patients younger than 38 years (14% in patients younger than 35 years and 12% in patients aged 35-37 years). The rates of successful treatments are low for patients older than 42 years. The multiple pregnancy rate (MPR) for IUI is approximately 8% [1632]. IUI is not recommended in couples with unexplained infertility, male factor and mild endometriosis, unless the couples have religious, cultural or social objections to proceed with IVF [1635].

Intra-uterine insemination with ovarian stimulation is a safe, cheaper, patient-friendly and non-inferior alternative to IVF in the management of couples with unexplained and mild male factor infertility [1631, 1632]. A recent RCT showed lower multiple pregnancy rates and comparable live birth rates in patients submitted to IUI with hormonal stimulation when compared to women undergoing IVF with single embryo transfer [1636]. Additionally, IUI was found to be a more cost-effective treatment than IVF for couples with unexplained or mild male subfertility [1637].

9.7.1.2 In vitro fertilisation IVF involves using controlled ovarian hyperstimulation to recruit multiple oocytes during each cycle from the female partner. Follicular development is monitored ultrasonically, and ova are harvested before ovulation with the use of US-guided needle aspiration. The recovered oocytes are mixed with processed semen to perform *in-vitro* fertilisation. The developing embryos are incubated for two to three days in culture and then placed trans-cervically into the uterus.

The rapid refinement of embryo cryopreservation methods has resulted in better perinatal outcomes of frozen-thawed embryo transfer (FET) and make it a viable alternative to fresh embryo transfer (ET) [1638, 1639]. FET

seems to be associated with lower risk of gestational complications than fresh ET. Individual approaches remain appropriate to balance the options of FET or fresh ET at present [1640].

Generally, only 20% to 30% of transferred embryos result in clinical pregnancies. The global PR and DR per aspiration for non-donor IVF is 24.0% and 17.6%, respectively [1634].

According to the NICE guidelines, IVF treatment is appropriate in cases of unexplained infertility for women who have not conceived after two years of regular unprotected sexual intercourse [1641].

9.7.1.3 Intracytoplasmic sperm injection is a procedure through which a single sperm is injected directly into the egg using a glass micropipette.

The difference between ICSI and IVF is the method used to achieve fertilisation. In conventional IVF, oocytes are incubated with sperm in a Petri dish, and the male gamete fertilises the oocyte naturally. In ICSI, the cumulus-oocyte complexes go through a denudation process in which the cumulus oophorus and corona radiata cells are removed mechanically or by an enzymatic process. This step is essential to enable microscopic evaluation of the oocyte regarding its maturity stage, as ICSI is performed only in metaphase II oocytes [1642]. A thin and delicate glass micropipette (injection needle) is used to immobilise and pick up morphologically normal sperm selected for injection. A single spermatozoon is aspirated by its tail into the injection needle, which is inserted through the zona pellucida into the oocyte cytoplasm. The spermatozoon is released at a cytoplasmic site sufficiently distant from the first polar body. During this process, the oocyte is held still by a glass micropipette [1642].

With this technique the oocyte can be fertilised independently of the morphology and/or motility of the spermatozoon injected.

Intracytoplasmic sperm injection is currently the most commonly used assisted reproductive technology, accounting for 70-80% of the cycles performed [1643].

The procedure was first used in cases of fertilisation failure after standard IVF or when an inadequate number of sperm cells were available. The consistency of fertilisation independent of the functional quality of the spermatozoon has extended the application of ICSI to immature spermatozoa retrieved surgically from the epididymis and testis [1644]. ICSI is the natural treatment for couples with severe male factor infertility and is also used for a number of non-male factor indications (Table 36) [1645].

Moreover, the need to denude the oocyte has allowed assessment of the nuclear maturity of the oocyte. ICSI is also preferred in conjunction with pre-implantation genetic diagnosis and has recently been used to treat HIV discordant couples, where there is a pressing need to minimise the exposure of the oocyte to a large number of spermatozoa [1644].

The global PR and DR per aspiration for ICSI is 26.2% and 19.0%, respectively [1634]. For all ages and with all the different sperm types used, fertilisation after ICSI is at approximately 70% to 80% and it ensures a clinical pregnancy rate of up to 45% [1643, 1644].

Existing evidence does not support ICSI in preference over IVF in the general non-male factor ART population; however, in couples with unexplained infertility, ICSI is associated with lower fertilisation failure rates than IVF [1645].

Overall, pregnancy outcomes from ICSI are comparable between epididymal and testicular sperm and also between fresh and frozen-thawed epididymal sperm in men with OA [1646]. However these results are from studies of low evidence [1645].

Sperm injection outcomes with fresh or frozen-thawed testicular sperm have also been compared in men with NOA. In a meta-analysis of 11 studies and 574 ICSI cycles, no statistically significant difference was observed between fresh and frozen-thawed testicular sperm with regards to fertilisation rate (RR 0.97, 95% CI 0.92-1.02) and clinical pregnancy rates (RR 1.00, 95% CI 0.75-1.33) [1647]. However, no meta-analysis was performed on data regarding implantation rate, miscarriage rate, and low birth rate.

Testicular sperm in men with raised DNA fragmentation in ejaculated sperm

The use of testicular sperm for ICSI is associated with possibly improved outcomes compared to ejaculated

sperm in men with high sperm DNA fragmentation [1200, 1645]. Men with unexplained infertility with raised DNA fragmentation may be considered for TESE after failure from ARTs, although they should be counselled that live birth rates are under reported in the literature and patients must weigh up the risks of performing an invasive procedure in a potentially normozoospermic or unexplained condition. The advantages of the use of testicular sperm in men with cryptozoospermia have not yet been confirmed in large scale randomised studies [1648].

In terms of a practical approach, Urologists may offer the use of testicular sperm in patients with high DNA fragmentation. However, patients should be counselled regarded the low levels of evidence for this (i.e., non-randomised studies). Furthermore, testicular sperm should only be used in this setting once the common causes of oxidative stress have been excluded including varicoceles, dietary/lifestyle factors and accessory gland infections.

Table 36: Fertilisation methods for male-factor and non-male factor infertility (adapted from [1645]**)**

	Fertilisation method
Male Factor Infertility	
Sperms derived from men with azoospermia	ICSI mandatory
Severe OAT	ICSI highly recommended
Moderate OAT	IVF and ICSI equally effective
Isolated teratozoospermia	IVF and ICSI equally effective
Absolute asthenozoospermia	ICSI mandatory
Globozoospermia	ICSI mandatory
Anti-sperm antibodies	IVF and ICSI equally effective
Sperm DNA fragmentation	ICSI recommended
Non-male factor infertility	
Unexplained infertility	Equally effective. Couples should be informed that ICSI improves fertilisation rates compared to IVF alone, but once fertilisation is achieved the pregnancy rate is no better than with IVF. It should be noted for clarification that in the absence of male factors, ICSI should not be offered in the first treatment cycle [1649].
General non-male factor population	Equally effective, slightly in favour of IVF
Poor quality oocytes and advanced maternal age	Equally effective, slightly in favour of IVF
Pre-implantational genetic testing	ICSI highly recommended
Poor responders	Equally effective, slightly in favour of IVF
Tubal ligation	IVF preferable
Sero-discordant couples	Equally effective

ICSI = intracytoplasmic sperm injection; IVF = in vitro fertilisation; OAT = oligo-asthenoter-atozoospermia

ICSI is carried out using viable sperm populations. A number of semen processing techniques have been developed to select the optimal sperm fraction for ICSI. The density gradient centrifugation (DGC) and the swim-up procedures have been used as standard semen preparation techniques for ICSI for more than two decades [1650]. However, these traditional sperm selection techniques are unable to select sperm fractions with optimal DNA integrity and functional characteristics. Advanced sperm selection techniques have been introduced to optimise the selection of high quality sperm for ICSI [1651]. These selection methods are based on sperm surface charge (electrophoresis and Zeta potential), apoptosis (magnetic-activated sperm cell sorting (MACS) and glass wool), membrane maturity (hyaluronic acid binding), or ultra-morphological sperm assessment [1652].

9.7.1.4 Intra-cytoplasmic morphologically selected sperm injection (IMSI) was first introduced in 2002 as a modification of the ICSI technique [1653]. This technology introduced the magnification of sperm to more than 6,000 times its size, the purpose of which is to perform the motile sperm organelle morphology examination (MSOME), a method used to select spermatozoa that have the choicest morphology in couples with the most severe male factor. Bartoov *et al.* showed that, for patients with histories of ICSI failure, the addition of IMSI resulted in a 60% pregnancy rate, compared with a 30% rate for patients not using IMSI [1654]. Moreover, the pregnancy rate following IVF-IMSI was significantly higher and the miscarriage rate significantly lower,

than in the routine IVF-ICSI procedure (60.0% vs. 25.0%, and 14% vs. 40%, respectively) [1655]. However, a meta-analysis reviewed nine RCTs evaluating 2,014 couples and concluded that the current evidence does not adequately support the use of IMSI [1656].

Because IMSI is also a costly procedure, more studies with larger sample sizes are needed to confirm its value before recommending it for ART.

9.7.1.5 PICSI technique: a selection based on membrane maturity of sperm

The human oocyte is surrounded by hyaluronic acid, which acts as a natural selector. In fact, only mature sperm that express receptors specific to HA can reach the oocyte and fertilise it. Those sperm have normal shapes, low DNA fragmentation rates, and low frequency of chromosomal aneuploidies [1657]. Several studies have attempted to verify whether sperm selection based on HA binding could affect IVF outcomes. A meta-analysis included six prospective randomised studies and one retrospective study, all of which used either the PICSI sperm selection dish (a plastic culture dish with microdots of HA hydro gel on its inner surface) or the Sperm Slow method (a viscous medium containing HA). No improvements in fertilisation and pregnancy rates were recorded, although embryo quality was superior in PICSI compared with conventional ICSI [1657]. A recent large-sample multicentre randomised trial provided conclusive evidence against the use of PICSI in ART (PICSI live birth rate versus ICSI: OR 1.12, 95% CI 0.95-1.34) [1658]. A time-lapse study found no difference in embryo development dynamics in oocytes fertilised via HA-ICSI vs. conventional ICSI [1659].

9.7.1.6 Magnetic-activated cell sorting (MACS) is an advanced sperm selection technique used to isolate sperm that do not show signs of apoptosis and, therefore, are presumed to have a lower rate of DNA damage [1651]. Use of MACS after density gradient centrifugation (DGC) has been found to improve sperm morphology and decrease DNA fragmentation and apoptotic markers, but it reduces the motility of the selected sperm [1651, 1652]. Magnetic-activated cell sorting failed to improve ICSI outcomes compared with DGC or swim-up, although a slightly higher pregnancy rate (RR) 1.5, 95% CI 1.14-1.98) was observed in MACS patients relative to the control group [1660]. No difference in implantation or miscarriage rate was noted (RR 1.03 [95% CI 0.8-1.31] and 2 [95% CI 0.19-20.9], respectively).

Finally, another randomised controlled trial performed on infants conceived via ovum-donation IVF cycles did not report any differences in terms of obstetrical and perinatal outcomes between pregnancies or babies conceived with sperm selected via MACS or swim-up [1661].

9.7.2 ***Safety***

The most significant risk of pre-implantation ART treatment is the ovarian hyperstimulation syndrome, a potentially life-threatening condition resulting from excessive ovarian stimulation during ART techniques, ranging from 0.6% to 5% in assisted reproduction cycles [1662].

Other problems include the risk of multiple pregnancies due to the transfer of more than one embryo and the associated risks to mother and baby, including multiple and preterm birth. The most prevalent maternal complications include pre-eclampsia, gestational diabetes, placenta previa, placental abruption, postpartum haemorrhage, and preterm labour and delivery [1663-1665]. The risks of foetal demise during the third trimester, perinatal mortality, preterm birth, and low birth weight increase with the number of foetuses in the pregnancy. The foetal consequences of preterm birth (cerebral palsy, retinopathy, and broncho-pulmonary dysplasia) and foetal growth restriction (polycythemia, hypoglycemia, and necrotizing enterocolitis) are significant [1666].

The average number of embryos transferred in fresh non-donor IVF and ICSI cycles in 2011 was 1.91, compared with 2.09 in 2008, 2.00 in 2009, and 1.95 in 2010, reflecting a continuing decrease from previous years. The average number of embryos transferred in frozen ET cycles decreased from 1.72 in 2008 to 1.65 in 2009 to 1.60 in 2010 and to 1.59 in 2011 [1667].

The global multiple birth rate for fresh cycle transfer has decreased from 21.5% in 2010 to 20.5% in 2011 and for frozen ET cycles from 12.0% to 11.5% [1634].

In 2011, the rate of early pregnancy loss was 20.1% after fresh ET, compared with 25.4% after frozen ET. Both rates showed wide regional variation [1634]. The multiple birth rates after fresh non-donor ET was 19.6% (twins) and 0.9% (triplets and higher order births); for frozen ET non-donor cycles, twin and triplet and higher order birth rates were 11.1% and 0.4%, respectively [1634].

Rates of premature delivery and perinatal mortality were lower for frozen ETs than for fresh ETs. The global preterm DR after non-donor fresh ET was 19.1%, and after frozen ET was 13.1%. The perinatal mortality rate per 1,000 births after non-donor fresh ET was 16.3 and after frozen ET was 8.6.

In terms of potential adverse effects of ICSI-conceived offspring, a greater neonatal morbidity, obstetric complications and congenital malformations compared to spontaneous conceptions [1668-1670]. Additionally, epigenetic disorders and impaired neurodevelopment have been observed in infants born using ICSI compared with naturally conceived children [1645]. Among singleton infants born at 37 weeks of gestation or later, those following IVF had a risk of low birth weight that was 2.6 times (95% CI 2.4-2.7) than in the general population (absolute risk of low birth weight with spontaneous versus resulting from IVF was 2.5% versus 6.5%) [1295]. Singleton infants after IVF were 39% more likely (adjusted RR of 1.39, 95% CI 1.21-1.59) to have a non-chromosomal birth defect (particularly gastrointestinal and musculoskeletal) compared with all other singleton births. No single ART procedure (e.g., ICSI, fresh, or frozen ETs) was found to substantially increase the risk of birth defects.

Analyses from the Massachusetts Outcome Study of ART reported a 50% increase (adjusted prevalence ratio of 1.5, 95% CI 1.3-1.6) in birth defects in infants after IVF vs. spontaneous pregnancy, and a 30% increase (adjusted prevalence ratio of 1.3, 95% CI 1.1-1.5) in birth defects in infants after subfertility vs. spontaneous pregnancy [1671-1673]. No difference in risk of cancer was found between ART-conceived children and those spontaneously conceived [1674].

Health differences between ICSI and IVF conceptions have not been comprehensively assessed and results are contradictory. Some authors found a significantly reduced risk of birth defects in IVF- compared to ICSI conceived infants [1298] (while two meta-analyses demonstrated no difference in risk of congenital malformations between IVF and ICSI conception) [1301, 1675]. Data about ICSI- and IVF-conceived adolescents or young adults is scarce but it seems that there is no difference in outcomes between the two techniques. Further research into health outcomes in adolescence and adulthood is required before conclusions can be drawn about the long-term safety of ICSI compared to IVF [1676].

10. LATE EFFECTS, SURVIVORSHIP AND MEN'S HEALTH

The EAU Guidelines Panel of Sexual and Reproductive Health have extensively reviewed the literature to provide guidance on: i) late effects of urological diseases (both occurring during childhood and adulthood) on male sexual and reproductive health; ii) late and long-term effects of cancers on male sexual and reproductive health; and, iii) future directions to support personalised medicine strategies for promotion and raising the awareness of overall male sexual and reproductive health.

A systematic literature search for original English-language publications and review articles published up to December 2019 was performed using both Pubmed and Google, yielding only a very limited number of papers addressing the role of health care professionals in supporting male patients who have suffered from cancers in terms of sexual and reproductive health, or the concept of Men's Health programmes.

Despite considerable public health initiatives over the past decades, the panel observed that there is still a significant gender gap between male and female in life expectancy [1677, 1678]. The main contributors to male mortality in Europe are non-communicable diseases (namely cardiovascular diseases [CVD)], cancer, diabetes and respiratory disease) and injuries [1679], as highlighted in a recent WHO report disproving the prevailing misconception that the higher rate of premature mortality amongst men is a natural phenomenon [1678, 1679].

The WHO report also addresses male sexual and reproductive health which is considered under reported, linking in particular male infertility, as a proxy for overall health, to serious diseases in men [1583, 1589, 1680-1684]. These data suggest that health care policies should redirect their focus to preventive strategies and in particular pay attention to follow-up of men with sexual and reproductive complaints [1685]. Considering that the infertile male seems to be at greater risk of death, simply because of their inability to become fathers, is unacceptable [1686]. The Panel aim to develop a concept of a more streamlined and holistic approach to Men's health.

For these guidelines, the panel aimed to challenge clinicians to look beyond the pathology of disorders alone and consider the potential associations with other health disorders; f.i. men with varicoceles have a higher incidence of heart disease, a higher risk of diabetes and hyperlipidaemia following diagnosis [1685]. A diagnosis of infertility may have a profound psychological impact on men (and their partners), potentially resulting in anxiety, enduring sadness, anger, and a sense of personal inadequacy and "unmet masculinity" [1688]. A combination of factors, personality, sociocultural background, and specific treatments/professional support, will determine how men cope with this diagnosis [1687].

The most common cancer among European men (excluding non-melanoma skin cancer) is PCa [351]. Due to new therapeutic approaches, survival rates have improved significantly [1689] and as men live longer, health-related quality of life and related sexual well-being will become increasingly important [1691]. Regardless of the type of treatment used [1692], sexual dysfunction is one of the most common post-treatment complications [342, 343, 1690].

Furthermore, relatively little is known about the relevance of fertility and fertility preservation strategies in cancer survivors [1693, 1694, 1695-1697]. In PCa, it has been documented that the psychological consequences persist, even after complete remission or cure and erectile function is restored [1698]. Therefore urologists dealing with sexual and reproductive health are primed to act as a vanguard for cancer survivorship programmes.

Finally, the relationship between ED and heart disease has been firmly established for well over two decades now [288, 289, 291, 1710-1713]. Cadiovascular disease is the leading cause of both male mortality and premature mortality [1699-1702]. Studies indicate that all major risk factors for CVD, including hypertension, smoking and elevated cholesterol are more prevalent in men than women [1703-1709]. Given that ED is an established early sign of atherosclerotic disease and predicts cardiovascular events as an independent factor [291], it provides urologists with the unique opportunity for CVD screening and health modification and to optimise CVD risk factors, whilst treating men's primary complaint (e.g., ED). Currently, both the EAU and AUA guidelines recommend screening for CVD risk factors in men with ED and late onset hypogonadism [1714-1716] (see sections 3.7.3 and 5.2).

There is clearly a need to prospectively collect data addressing all aspects of male health, including CVD screening protocols and to assess the impact of primary and secondary preventive strategies. The EAU Guidelines panel off Male sexual and reproductive health aims to promote and develop a long-term strategy to raise men's health at a global level.

12. CONFLICT OF INTEREST

All members of the EAU Sexual and Reproductive Health Guidelines working panel have provided disclosure statements on all relationships that they have that might be perceived to be a potential source of conflict of interest. This information is publically accessible through the European Association of Urology website http://www.uroweb.org/guidelines/. This document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

13. CITATION INFORMATION

The format in which to cite the EAU Guidelines will vary depending on the style guide of the journal in which the citation appears. Accordingly, the number of authors or whether, for instance, to include the publisher, location, or an ISBN number may vary.

The compilation of the complete Guidelines should be referenced as:
EAU Guidelines. Edn. presented at the EAU Annual Congress Amsterdam 2020. ISBN 978-94-92671-07-3.

If a publisher and/or location is required, include:
EAU Guidelines Office, Arnhem, The Netherlands. http://uroweb.org/guidelines/compilations-of-all-guidelines/

References to individual guidelines should be structured in the following way:
Contributors' names. Title of resource. Publication type. ISBN. Publisher and publisher location, year.

European Association of Urology

TABLE OF CONTENTS PAGE

1. INTRODUCTION

1.1 Aim and objectives

The European Association of Urology (EAU) Urological Infections Guidelines Panel has compiled these clinical guidelines to provide medical professionals with evidence-based information and recommendations for the prevention and treatment of urinary tract infections (UTIs) and male accessory gland infections. These guidelines also aim to address the important public health aspects of infection control and antimicrobial stewardship. Separate EAU guidelines documents are available addressing paediatric urological infections [1] and infections in patients with neurological urinary tract dysfunction [2].

It must be emphasised that clinical guidelines present the best evidence available to the experts. However, following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The EAU Urological Infections Guidelines Panel consists of a multi-disciplinary group of urologists, with particular expertise in this area, an infectious disease specialist and a clinical microbiologist. All experts involved in the production of this document have submitted potential conflict of interest statements, which can be viewed on the EAU website Uroweb: http://uroweb.org/guideline/urological-infections/.

1.3 Available publications

A quick reference document, the Pocket Guidelines, is available in print and as an app for iOS and Android devices. These are abridged versions, which may require consultation together with the full text version. All documents are accessible through the EAU website Uroweb: http://uroweb.org/guideline/urological-infections/.

1.4 Publication history

The Urological Infections Guidelines were first published in 2001. This 2020 document presents a limited update of the 2019 publication.

2. METHODS

2.1 Introduction

For the 2020 Urological Infections Guidelines, new and relevant evidence was identified, collated and appraised through a structured assessment of the literature for sections 3.4, 3.6, 3.7 and 3.10. Broad and comprehensive literature searches, covering these sections were performed. Databases searched included Medline, EMBASE, and the Cochrane Libraries. The time frames covered and the number of unique records identified, retrieved and screened for relevance for each section were:

Section	No. of unique records	Search time frame
3.4 Uncomplicated cystitis	694	Jan 1st 2014 – Feb 1st 2019
3.7 Complicated UTI	1,331	
3.10 Urethritis	488	
3.6 Uncomplicated pyelonephritis	1,006	Jan 1st 2015 – Feb 1st 2019

Detailed search strategies are available online: http://uroweb.org/guideline/urological-infections/?type=-appendices-publications. For the 2021 Urological Infections Guidelines the following sections will be updated:

- 3.5 Recurrent UTI;
- 3.8 Catheter associated UTI.

The 2020 edition of the EAU Guidelines uses a modified GRADE methodology [3]. For each recommendation within the guidelines there is an accompanying online strength rating form which addresses a number of key elements namely:

1. the overall quality of the evidence which exists for the recommendation, references used in this text are graded according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [4];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact of patient values and preferences on the intervention;
6. the certainty of those patient values and preferences.

These key elements are the basis which panels use to define the strength rating of each recommendation. The strength of each recommendation is represented by the words 'strong' or 'weak' [5]. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and nature and variability of patient values and preferences.

Additional information can be found in the general Methodology section of this print, and on the EAU website; http://www.uroweb.org/guideline/. A list of associations endorsing the EAU Guidelines can also be viewed online at the above address.

2.2 Review

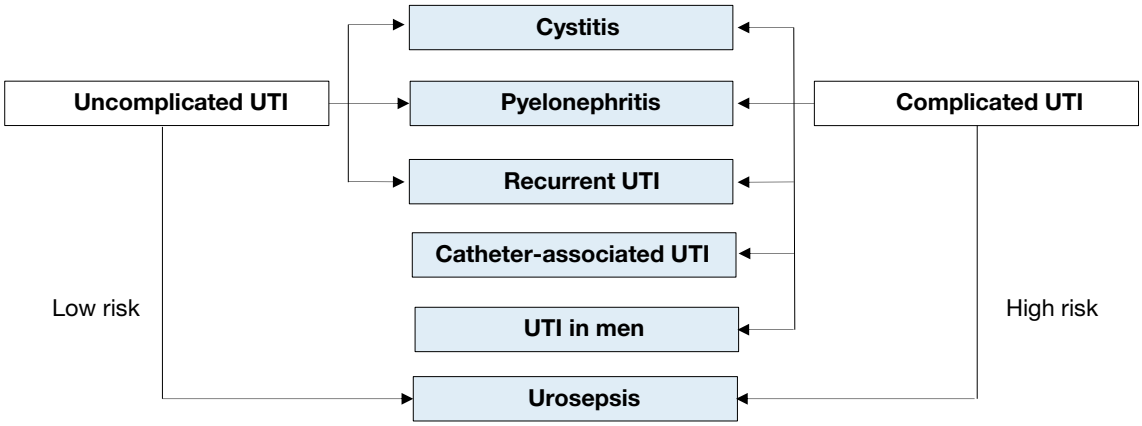
This document was subject to independent peer review prior to publication in 2019.

3. THE GUIDELINE

3.1 Classification

Different classification systems of UTI exist. Most widely used are those developed by the Centres for Disease Control and Prevention (CDC) [6], Infectious Diseases Society of America (IDSA) [7], European Society of Clinical Microbiology and Infectious Diseases (ESCMID) [8] as well as the U.S. Food and Drug Administration (FDA) [9, 10]. Current UTI guidelines frequently use the concept of uncomplicated and complicated UTI with a number of modifications (Figure 1). In 2011 the EAU Section of Infections in Urology proposed the ORENUC classification system based on the clinical presentation of the UTI, the anatomical level of the UTI, the grade of severity of the infection, the categorisation of risk factors and availability of appropriate antimicrobial therapy [11].

Figure 1: Concept of uncomplicated and complicated UTI



The following classification of UTIs is adopted in the EAU Urological Infections Guidelines:

Classification of UTI	
Uncomplicated UTIs	Acute, sporadic or recurrent lower (uncomplicated cystitis) and/or upper (uncomplicated pyelonephritis) UTI, limited to non-pregnant women with no known relevant anatomical and functional abnormalities within the urinary tract or comorbidities.
Complicated UTIs	All UTIs which are not defined as uncomplicated. Meaning in a narrower sense UTIs in a patient with an increased chance of a complicated course: i.e. all men, pregnant women, patients with relevant anatomical or functional abnormalities of the urinary tract, indwelling urinary catheters, renal diseases, and/or with other concomitant immunocompromising diseases for example, diabetes.
Recurrent UTIs	Recurrences of uncomplicated and/or complicated UTIs, with a frequency of at least three UTIs/year or two UTIs in the last six months.
Catheter-associated UTIs	Catheter-associated urinary tract infection (CA-UTI) refers to UTIs occurring in a person whose urinary tract is currently catheterised or has had a catheter in place within the past 48 hours.
Urosepsis	Urosepsis is defined as life threatening organ dysfunction caused by a dysregulated host response to infection originating from the urinary tract and/or male genital organs [12].

3.2 Antimicrobial Stewardship

Although the benefits to patients of antibiotic use are clear, overuse and misuse have contributed to the growing problem of resistance amongst uropathogenic bacteria, which is a serious threat to public health [13, 14]. In acute care hospitals, 20-50% of prescribed antibiotics are either unnecessary or inappropriate [15]. In response, a worldwide initiative seeks to incorporate Antimicrobial Stewardship programs in healthcare [16]. Antimicrobial Stewardship aims to optimise clinical outcomes and ensure cost-effective therapy whilst minimising unintended consequences of antimicrobial use such as healthcare associated infections including *Clostridium difficile*, toxicity, selection of virulent organisms and emergence of resistant bacterial strains [17].

Stewardship programs have two main sets of actions. The first set mandates use of recommended care at the patient level conforming to guidelines. The second set describes strategies to achieve adherence to the mandated guidance. These include persuasive actions such as education and feedback together with restricting availability linked to local formularies. A Cochrane review of effectiveness of interventions to improve antibiotic prescribing practices for hospital inpatients, updated in 2017, found high-certainty evidence that such interventions are effective in increasing adherence with antibiotic policy leading to reduced antibiotic treatment duration and that it may also reduce hospital stay. The review found no evidence that reduced antibiotic usage increased mortality [18].

The important components of antimicrobial stewardship programs are [19]:

- regular training of staff in best use of antimicrobial agents;
- adherence to local, national or international guidelines;
- regular ward visits and consultation with infectious diseases physicians and clinical microbiologists;
- audit of adherence and treatment outcomes;
- regular monitoring and feedback to prescribers of their performance and local pathogen resistance profiles.

A 2016 systematic review of evidence for effectiveness of various Antimicrobial Stewardship interventions in healthcare institutions identified 145 studies of nine Stewardship objectives. Guideline-driven empirical therapy using a restricted choice of antibiotics and including de-escalation, intravenous to oral switch, therapeutic drug monitoring, and bedside consultation resulted in a 35% (95% CI 20-46%) relative risk reduction (RRR) in mortality. Use of de-escalation (tailoring to a more narrow spectrum agent), showed a RRR of 56% (95% CI 34 – 70%) for mortality [20].

To facilitate local initiatives and audit, a set of valid, reliable, and applicable indicators of the quality of antibiotic use in the treatment of hospitalised patients with complicated UTI was developed [21]. Its use in the Netherlands appeared to result in shortened hospital stay [22]. A literature search of Pubmed from April 2014 [20], to February 2017 identified no further randomised controlled trials (RCTs) relating to stewardship

programmes for UTIs. Studies to provide high-quality evidence of effectiveness of Stewardship programmes in urology patients are urgently needed.

3.3 Asymptomatic bacteriuria in adults

*3.3.1 **Evidence question***

What is the most effective management for people with asymptomatic bacteriuria?

*3.3.2 **Background***

Urinary growth of bacteria in an asymptomatic individual (asymptomatic bacteriuria - ABU) is common, and corresponds to a commensal colonisation [23]. Clinical studies have shown that ABU may protect against superinfecting symptomatic UTI, thus treatment of ABU should be performed only in cases of proven benefit for the patient to avoid the risk of selecting antimicrobial resistance and eradicating a potentially protective ABU strain [24, 25]. The aim of this section is to support the clinician in deciding when ABU should or should not be treated.

*3.3.3 **Epidemiology, aetiology and pathophysiology***

Asymptomatic bacteriuria occurs in an estimated 1-5% of healthy pre-menopausal females. Increasing to 4-19% in otherwise healthy elderly females and men, 0.7-27% in patients with diabetes, 2-10% in pregnant women, 15-50% in institutionalised elderly populations, and in 23-89% in patients with spinal cord injuries [26]. Asymptomatic bacteriuria in younger men is uncommon, but when detected, chronic bacterial prostatitis must be considered. The spectrum of bacteria in ABU is similar to species found in uncomplicated or complicated UTIs, depending on the presence of risk factors (see sections 3.4 and 3.7).

*3.3.4 **Diagnostic evaluation***

Asymptomatic bacteriuria in an individual without urinary tract symptoms is defined by a mid-stream sample of urine showing bacterial growth ≥ 10^5 cfu/mL in two consecutive samples in women [27] and in one single sample in men [28]. In a single catheterised sample, bacterial growth may be as low as 10^2 cfu/mL to be considered representing true bacteriuria in both men and women [26, 29]. Cystoscopy and/or imaging of the upper urinary tract is not mandatory if the medical history is otherwise without remark. If persistent growth of urease producing bacteria, i.e. *Proteus mirabilis* is detected, stone formation in the urinary tract must be excluded [30]. In men, a digital rectal examination (DRE) has to be performed to investigate the possibility of prostate diseases (see section 3.11).

*3.3.5 **Evidence summary***

A systematic search of the literature from January 2000 to November 2016 identified 3,582 titles of which 224 were selected for full text review and 50 were included [31]. For the subgroups of pregnancy, prior to urologic surgeries, post-menopausal women and institutionalised elderly patients only data from RCTs were included, on which a meta-analysis was performed [31]. For the other subgroups non-RCTs were also included in the narrative analysis [31]. The following patient populations were not covered by the systematic review: immuno-compromised patients; patients with candiduria; patients with dysfunctional and/or reconstructed lower urinary tracts; and patients with indwelling catheters. For these groups the guideline was updated using a structured PubMed search.

*3.3.6 **Disease management***

3.3.6.1 Patients without identified risk factors

Asymptomatic bacteriuria does not cause renal disease or damage [32]. Only one prospective, non-randomised study investigated the effect of treatment of ABU in adult, non-diabetic, non-pregnant women [33], and found no difference in the rate of symptomatic UTIs. Furthermore, as the treatment of ABU has been proven to be unnecessary in most high-risk patient subgroups, there is panel consensus that the results of these subgroups can also be applied to patients without identified risk factors. Therefore, screening and treatment of ABU is not recommended in patients without risk factors.

3.3.6.2 Patients with ABU and recurrent UTI, otherwise healthy

One RCT investigated the effect of ABU treatment in female patients with recurrent symptomatic UTI without identified risk factors [25] and demonstrated that treatment of ABU increases the risk for a subsequent symptomatic UTI episode, compared to non-treated patients (RR 0.28, 95% CI 0.21 to 0.38; n=673). This protective effect of spontaneously developed ABU can be used as part of prevention in female patients with recurrent symptomatic UTI; therefore, treatment of ABU is not recommended.

3.3.6.3 Pregnant women

3.3.6.3.1 Is treatment of ABU beneficial in pregnant women?

Twelve RCTs comparing antibiotic treatments of ABU with placebo controls or no treatment [34-45], with different antibiotic doses and regimens were identified, ten published before 1988 and one in 2015. Eleven RCTs (n=2,002) reported on the rate of symptomatic UTIs [34, 36-44, 46]. Antibiotic treatment significantly reduced the number of symptomatic UTIs compared to placebo or no treatment (average RR 0.22, 95% CI 0.12 to 0.40).

Six RCTs reported on the resolution of bacteriuria [34-36, 38, 41, 43]. Antibiotic treatment was effective in the resolution of bacteriuria compared to placebo (average RR 2.99, 95% CI 1.65 to 5.39; n=716). Eight RCTs reported on the rate of low birthweights [34, 36-39, 42, 45, 46]. Antibiotic treatment was associated with lower rates of low birthweight compared to placebo or no treatment (average RR 0.58, 95% CI 0.36 to 0.94; n=1689). Four RCTs reported on the rate of preterm deliveries [42, 43, 45, 46]. Antibiotic treatment was associated with lower rates of preterm delivery compared to placebo or no treatment (average RR 0.34, 95% CI 0.18 to 0.66; n=854).

Based on the beneficial maternal and foetal effects of antibiotic treatment pregnant women should be screened and treated for ABU. However, the panel would like to emphasise that most available studies have low methodological quality and are from the 60s to 80s. Diagnostic and treatment protocols and accessibility to medical services have dramatically changed since then; therefore, the quality of evidence for this recommendation is low. In a newer study of higher methodological quality the beneficial effects of antibiotic treatment are not as evident [46]. Therefore, it is advisable to consult national recommendations for pregnant women.

3.3.6.3.2 Which treatment duration should be applied to treat ABU in pregnancy?

Sixteen RCTs comparing the efficacy of different antibiotic treatments in pregnant women with ABU were identified [47-62]. There was significant heterogeneity amongst the studies. Studies compared different antibiotic regimens or the same antibiotic regimens with different durations. The duration of treatment ranged from single dose to continuous treatment (until delivery). For practical purposes the grouping strategy used by the previously published Cochrane Review by Widmer et al. was adopted with some modifications [63]. The following treatment groups were used for comparison:

1. single dose (single day);
2. short course (2-7 days);
3. long course (8-14 days);
4. continuous (until delivery).

Nine studies compared single dose to short course treatment [48, 52, 53, 57-62], one study compared single dose to long course treatment [56] and one study compared long course to continuous treatment [49]. As long term and continuous antibiotic treatment is not used in current practice, only studies comparing single dose to standard short course treatment are presented.

3.3.6.3.2.1 Single dose vs. short course treatment

Three RCTs reported on the rate of symptomatic UTIs [52, 61, 62], with no significant difference between the two durations (average RR 1.07, 95% CI 0.47 to 2.47; n=891). Nine RCTs reported on the rate of ABU resolution [48, 52, 53, 57-62], with no significant difference between the two durations (average RR 0.97, 95% CI 0.89 to 1.07; n=1,268). Six RCTs reported on the rate of side effects [48, 52, 57, 58, 60, 61]. Single dose treatment was associated with significantly less side effects compared to short course treatment (average RR 0.40, 95% CI 0.22 to 0.72; n=458). Three RCTs reported on the rate of preterm deliveries [52, 54, 62], with no significant difference between the two durations (average RR 1.16, 95% CI 0.75 to 1.78; n=814). One RCT reported on the rate of low birthweights [62]. There were significantly more babies with low birthweight in the single dose duration compared to short course treatment (average RR 1.65, 95% CI 1.06 to 2.57; n=714).

According to the data analysis, single dose treatment was associated with a significantly lower rate of side effects but a significantly higher rate of low birthweight. Therefore, standard short course treatment should be applied to treat ABU in pregnancy; however, it should be emphasised that the overall quality of the scientific evidence backing this recommendation is low.

3.3.6.4 Patients with identified risk-factors

3.3.6.4.1 Diabetes mellitus

Diabetes mellitus, even when well regulated, is reported to correlate to a higher frequency of ABU [64]. One RCT demonstrated that eradicating ABU did not reduce the risk of symptomatic UTI and infectious complications in patients with diabetes mellitus. The time to first symptomatic episode was also similar in both

groups. Furthermore, untreated ABU did not correlate to diabetic nephropathy [65]. Screening and treatment of ABU in well-controlled diabetes mellitus is therefore not recommended. However, poorly regulated diabetes is a risk factor for symptomatic UTI and infectious complications.

3.3.6.4.2 ABU in post-menopausal women

Elderly women have an increased incidence of ABU [66]. Four RCTs compared antibiotic treatment of ABU with placebo controls or no treatment, in a post-menopausal female population, with different antibiotic doses and regimens [67-70]. Women in these studies were mostly nursing home residents, which may bias the results of this analysis. Three RCTs reported on the rate of symptomatic UTIs (average RR 0.71, 95% CI 0.49 to 1.05; 208 women) and the resolution of bacteriuria (average RR 1.28, 95% CI 0.50 to 3.24; 203 women) [52, 61, 62], with no significant benefit of antibiotic treatment. Therefore, ABU in post-menopausal women does not require treatment, and should be managed as for pre-menopausal women.

3.3.6.4.3 Elderly institutionalised patients

The rate of ABU is 15-50% in elderly institutionalised patients [71]. Differential diagnosis of ABU from symptomatic UTI is difficult in the multi-diseased and mentally deteriorated patient, and is probably a cause of unnecessary antibiotic treatment [72, 73]. Seven RCTs compared antibiotic treatment of ABU with placebo controls or no treatment in elderly patients, with different antibiotic doses and regimens [67-70, 74-76].

Three RCTs reported on the rate of symptomatic UTIs [67, 69, 74]. Antibiotic treatment was not significantly beneficial in reducing the rate of symptomatic UTIs compared to placebo or no treatment (average RR 0.68, 95% CI 0.46 to 1.00; n=210). Six RCTs reported on the resolution of bacteriuria [67, 69, 70, 74-76]. There was no benefit of antibiotic treatment compared to placebo in the resolution of ABU (average RR 1.33, 95% CI 0.63 to 2.79; n=328). One RCT compared the rates of incontinence in this patient group before and after the eradication of ABU, and found no effect of antibiotic treatment [77]. Therefore, screening and treatment of ABU is not recommended in this patient group.

3.3.6.4.4 Patients with renal transplants

Two RCTs and two retrospective studies compared the effect of antibiotic treatment to no treatment in renal transplant patients [78-81]. Meta-analysis of the two RCTs did not find antibiotic treatment beneficial in terms of reducing symptomatic UTIs (RR 0.86, 95% CI 0.51 to 1.45; n=200). The two retrospective studies reached the same conclusion. Furthermore, there were no significant differences in the rate of ABU clearance, graft loss or change in renal function during long-term follow-up up to 24 months [78-81]. Therefore, treatment of ABU is not recommended in renal transplant recipients.

3.3.6.4.5 Patients with dysfunctional and/or reconstructed lower urinary tracts

Patients with lower urinary tract dysfunction (LUTD) (e.g. neurogenic bladder patients secondary to multiple sclerosis, spinal cord injury patients, patients with incomplete bladder emptying, patients with neo-bladder and ileo-cystoplasty, patients using clean intermittent catheterisation (CIC), and patients with ileal conduits, orthotopic bladder replacement and continent reservoirs) frequently become colonised [82, 83]. Studies have shown no benefit in ABU treatment in these patient groups [84, 85]. Furthermore, in LUTD patients who do not spontaneously develop ABU, deliberate colonisation with an ABU strain (*Escherichia coli* 83972) has shown a protective effect against symptomatic recurrences [84, 85]. Screening and treatment of ABU in these patient groups is therefore, not recommended. If these patient groups develop recurrent symptomatic UTI (see section 3.5) the potential protective effect of a spontaneously developed ABU against lower UTI must be considered before any treatment.

3.3.6.4.6 Patients with catheters in the urinary tract

Patients with indwelling or suprapubic catheters and nephrostomy tubes invariably become carriers of ABU, with antibiotic treatment showing no benefit [86]. This is also applicable for patients with ABU and indwelling ureteral stents [87]. Routine treatment of catheter-associated bacteriuria is not recommended. For detailed recommendations see section 3.8.

3.3.6.4.7 Patients with ABU subjected to catheter placements/exchanges

In patients subjected to uncomplicated placement/exchanges of indwelling urethral catheters ABU is not considered a risk factor and should not be screened or treated [88]. In patients subjected to placement/exchanges of nephrostomy tubes and indwelling ureteral stents, ABU is considered a risk factor for infectious complications [89]; therefore, screening and treatment prior to the procedure is recommended.

3.3.6.4.8 Immuno-compromised and severely diseased patients, patients with candiduria

These patient groups have to be considered individually and the benefit of screening and treatment of ABU

should be reviewed in each case. Patients with asymptomatic candiduria may, although not necessarily, have an underlying disorder or defect. Treatment of asymptomatic candiduria is not recommended [90].

3.3.6.5 Prior to urological surgery

In diagnostic and therapeutic procedures not entering the urinary tract, ABU is generally not considered as a risk factor, and screening and treatment are not considered necessary. On the other hand, in procedures entering the urinary tract and breaching the mucosa, particularly in endoscopic urological surgery, bacteriuria is a definite risk factor.

Two RCTs [91, 92] and two prospective non-randomised studies [93, 94] compared the effect of antibiotic treatment to no treatment before transurethral prostate or bladder tumour resections. Antibiotic treatment significantly reduced the number of post-operative symptomatic UTIs compared to no treatment in the meta-analysis of the two RCTs (average RR 0.20, 95% CI 0.05 to 0.86; n=167). The rates of post-operative fever and septicaemia were also significantly lower in case of antibiotic treatment compared to no treatment in the two RCTs. One RCT including patients with spinal cord injury undergoing elective endoscopic urological surgeries found no significant difference in the rate of post-operative UTIs between single-dose or 3-5 days short term pre-operative antibiotic treatment of ABU [95].

A urine culture must therefore be taken prior to such interventions and in case of ABU, pre-operative treatment is recommended.

3.3.6.6 Prior to orthopaedic surgery

One RCT (n=471) and one multicentre cohort study (n=303) comparing the treatment of ABU with no treatment prior to orthopaedic surgery (hip arthroplasty/hemiarthroplasty or total knee arthroplasty) were identified [96, 97]. Neither of the studies showed a beneficial effect of antibiotic treatment in terms of prosthetic joint infection (3.8% vs. 0% and 3.9% vs. 4.7%, respectively). The cohort study reported no significant difference in the rate of post-operative symptomatic UTI (0.65% vs. 2.7%) [97]. Therefore, treatment of bacteriuria is not recommended prior to arthroplasty surgery.

3.3.6.7 Pharmacological management

If the decision is taken to eradicate ABU, the same choice of antibiotics and treatment duration as in symptomatic uncomplicated (section 3.4.4.4) or complicated (section 3.7.5) UTI can be given, depending on gender, medical background and presence of complicating factors. Treatment should be tailored and not empirical.

*3.3.7 **Follow-up***

There are no studies focusing on follow-up after treatment of ABU.

*3.3.8 **Summary of evidence and recommendations for the management of ABU***

Summary of evidence	**LE**
Treatment of asymptomatic bacteriuria is not beneficial in the following conditions:	
• women without risk factors;	3b
• patients with well-regulated diabetes mellitus;	1b
• post-menopausal women;	1a
• elderly institutionalised patients;	1a
• patients with dysfunctional and/or reconstructed lower urinary tracts;	2b
• patients with renal transplants;	1a
• patients prior to arthoplasty surgeries.	1b
Treatment of asymptomatic bacteriuria is harmful in patients with recurrent urinary tract infections.	1b
Treatment of asymptomatic bacteriuria is beneficial prior to urological procedures breaching the mucosa.	1a
Treatment of asymptomatic bacteriuria in pregnant women was found to be beneficial by meta-analysis of the available evidence; however, most studies are old. A recent study reported lower rates of pyelonephritis in low-risk women.	1a

Recommendations	Strength rating
Do not screen or treat asymptomatic bacteriuria in the following conditions: • women without risk factors; • patients with well-regulated diabetes mellitus; • post-menopausal women; • elderly institutionalised patients; • patients with dysfunctional and/or reconstructed lower urinary tracts; • patients with renal transplants; • patients prior to arthoplasty surgeries; • patients with recurrent urinary tract infections.	Strong
Screen for and treat asymptomatic bacteriuria prior to urological procedures breaching the mucosa.	Strong
Screen for and treat asymptomatic bacteriuria in pregnant women with standard short course treatment.	Weak

3.4 Uncomplicated cystitis

*3.4.1 **Introduction***

Uncomplicated cystitis is defined as acute, sporadic or recurrent cystitis limited to non-pregnant women with no known relevant anatomical and functional abnormalities within the urinary tract or comorbidities.

*3.4.2 **Epidemiology, aetiology and pathophysiology***

Almost half of all women will experience at least one episode of cystitis during their lifetime. Nearly one in three women will have had at least one episode of cystitis by the age of 24 years [98]. Risk factors include sexual intercourse, use of spermicides, a new sexual partner, a mother with a history of UTI and a history of UTI during childhood. The majority of cases of uncomplicated cystitis are caused by *E. coli*.

*3.4.3 **Diagnostic evaluation***

3.4.3.1 Clinical diagnosis

The diagnosis of uncomplicated cystitis can be made with a high probability based on a focused history of lower urinary tract symptoms (dysuria, frequency and urgency) and the absence of vaginal discharge [99, 100]. In elderly women genitourinary symptoms are not necessarily related to cystitis [101, 102].

3.4.3.2 Differential diagnosis

Uncomplicated cystitis should be differentiated from ABU, which is considered not to be infection but rather a commensal colonisation, which should not be treated and therefore not screened for, except if it is considered a risk factor in clearly defined situations (see section 3.3).

3.4.3.3 Laboratory diagnosis

In patients presenting with typical symptoms of an uncomplicated cystitis urine analysis (i.e. urine culture, dip stick testing, etc.) leads only to a minimal increase in diagnostic accuracy [103]. However, if the diagnosis is unclear dipstick analysis can increase the likelihood of an uncomplicated cystitis diagnosis [104, 105]. Taking a urine culture is recommended in patients with atypical symptoms, as well as those who fail to respond to appropriate antimicrobial therapy [106, 107].

3.4.3.4 Summary of evidence and recommendations for the diagnostic evaluation of uncomplicated cystitis

Summary of evidence	LE
An accurate diagnosis of uncomplicated cystitis can be based on a focused history of lower urinary tract symptoms and the absence of vaginal discharge or irritation.	2b

Recommendations	Strength rating
Diagnose uncomplicated cystitis in women who have no other risk factors for complicated urinary tract infections based on: • a focused history of lower urinary tract symptoms (dysuria, frequency and urgency); • the absence of vaginal discharge or irritation.	Strong
Use urine dipstick testing for diagnosis of acute uncomplicated cystitis.	Weak
Urine cultures should be done in the following situations: • suspected acute pyelonephritis; • symptoms that do not resolve or recur within four weeks after the completion of treatment; • women who present with atypical symptoms; • pregnant women.	Strong

*3.4.4 **Disease management***

Antimicrobial therapy is recommended because clinical success is significantly more likely in women treated with antimicrobials compared with placebo [108]. In female patients with mild to moderate symptoms, symptomatic therapy (e.g. Ibuprofen), as an alternative to antimicrobial treatment, may be considered in consultation with individual patients [109-112]. The choice of antimicrobial therapy should be guided by [99]:

- spectrum and susceptibility patterns of the aetiological pathogens;
- efficacy for the particular indication in clinical studies;
- tolerability and adverse reactions;
- adverse ecological effects;
- costs;
- availability.

According to these principles and the available susceptibility patterns in Europe, oral treatment with fosfomycin trometamol 3 g single dose, pivmecillinam 400 mg three times a day for three to five days, and nitrofurantoin (e.g. nitrofurantoin monohydrate/macrocrystals 100 mg twice daily for five days), should be considered for first-line treatment, when available [113-116].

Alternative antimicrobials include trimethoprim alone or combined with a sulphonamide. Co-trimoxazole (160/800 mg twice daily for three days) or trimethoprim (200 mg twice daily for five days) should only be considered as drugs of first choice in areas with known resistance rates for *E. coli* of < 20% [117, 118].

Aminopenicillins are no longer suitable for empirical therapy because of worldwide high *E. coli* resistance. Aminopenicillins in combination with a beta-lactamase inhibitor such as ampicillin/sulbactam or amoxicillin/clavulanic acid and oral cephalosporins are not recommended for empirical therapy due to ecological collateral damage, but may be used in selected cases [119, 120].

Important notice:

On March 11, 2019 the European Commission implemented stringent regulatory conditions regarding the use of fluoroquinolones due to their disabling and potentially long-lasting side effects [121]. This legally binding decision is applicable in all EU countries. National authorities have been urged to enforce this ruling and to take all appropriate measures to promote the correct use of this class of antibiotics. In uncomplicated cystitis a fluoroquinolone should only be used when it is considered inappropriate to use other antibacterial agents that are commonly recommended for the treatment of these infections [121].

3.4.4.1 Cystitis in pregnancy

Short courses of antimicrobial therapy can also be considered for treatment of cystitis in pregnancy [122], but not all antimicrobials are suitable during pregnancy. In general, penicillins, cephalosporins, fosfomycin, nitrofurantoin (not in case of glucose-6-phosphate dehydrogenase deficiency and during the end of pregnancy), trimethoprim (not in the first trimenon) and sulphonamides (not in the last trimenon), can be considered.

3.4.4.2 Cystitis in men

Cystitis in men without involvement of the prostate is uncommon and should be classed as a complicated infection. Therefore, treatment with antimicrobials penetrating into the prostate tissue is needed in males with symptoms of UTI. A treatment duration of at least seven days is recommended, preferably with trimethoprim sulfamethoxazole or a fluoroquinolone if in accordance with susceptibility testing (see section 3.4.4.4) [123].

3.4.4.3 Renal insufficiency

In patients with renal insufficiency the choice of antimicrobials may be influenced by decreased renal excretion; however, most antimicrobials, have a wide therapeutic index. No adjustment of dose is necessary until glomerular filtration rate (GFR) is < 20 mL/min, with the exception of antimicrobials with nephrotoxic potential, e.g. aminoglycosides. The combination of loop diuretics (e.g. furosemide) and a cephalosporin is nephrotoxic. Nitrofurantoin is contraindicated in patients with an estimated glomerular filtration rate (eGFR) of less than 30 ml/min/1.73m2 as accumulation of the drug leads to increased side effects as well as reduced urinary tract recovery, with the risk of treatment failure [124].

3.4.4.4 Summary of evidence and recommendations for antimicrobial therapy for uncomplicated cystitis

Summary of evidence	**LE**
Clinical success for the treatment of uncomplicated cystitis is significantly more likely in women treated with antimicrobials than placebo.	1b
Aminopenicillins are no longer suitable for antimicrobial therapy in uncomplicated cystitis because of negative ecological effects, high resistance rates and their increased selection for extended spectrum beta-lactamase (ESBL)-producing bacteria.	3

Recommendations	**Strength rating**
Prescribe fosfomycin trometamol, pivmecillinam or nitrofurantoin as first-line treatment for uncomplicated cystitis in women.	Strong
Do not use aminopenicillins or fluoroquinolones to treat uncomplicated cystitis.	Strong

Table 1: Suggested regimens for antimicrobial therapy in uncomplicated cystitis

Antimicrobial	**Daily dose**	**Duration of therapy**	**Comments**
First-line women			
Fosfomycin trometamol	3 g SD	1 day	Recommended only in women with uncomplicated cystitis.
Nitrofurantoin macrocrystal	50-100 mg four times a day	5 days	
Nitrofurantoin monohydrate/ macrocrystals	100 mg b.i.d	5 days	
Nitrofurantoin macrocrystal prolonged release	100 mg b.i.d	5 days	
Pivmecillinam	400 mg t.i.d	3-5 days	
Alternatives			
Cephalosporins (e.g. cefadroxil)	500 mg b.i.d	3 days	Or comparable
If the local resistance pattern for E. coli is < 20%			
Trimethoprim	200 mg b.i.d	5 days	Not in the first trimenon of pregnancy
Trimethoprim-sulphamethoxazole	160/800 mg b.i.d	3 days	Not in the last trimenon of pregnancy
Treatment in men			
Trimethoprim-sulphamethoxazole	160/800 mg b.i.d	7 days	Restricted to men, fluoroquinolones can also be prescribed in accordance with local susceptibility testing.

SD = single dose; b.i.d = twice daily; t.i.d = three times daily.

3.4.5 ***Follow-up***

Routine post-treatment urinalysis or urine cultures in asymptomatic patients are not indicated [26]. In women whose symptoms do not resolve by end of treatment, and in those whose symptoms resolve but recur within two weeks, urine culture and antimicrobial susceptibility testing should be performed [125]. For therapy in this situation, one should assume that the infecting organism is not susceptible to the agent originally used. Retreatment with a seven-day regimen using another agent should be considered [125].

3.5 Recurrent UTIs

*3.5.1 **Introduction***

Recurrent UTIs (rUTIs) are recurrences of uncomplicated and/or complicated UTIs, with a frequency of at least three UTIs/year or two UTIs in the last six months. Although rUTIs include both lower tract infection (cystitis) and upper tract infection (pyelonephritis), repeated pyelonephritis should prompt consideration of a complicated aetiology.

*3.5.2 **Diagnostic evaluation***

Recurrent UTIs are common. Risk factors are outlined in Table 2. Diagnosis of rUTI should be confirmed by urine culture. An extensive routine workup including cystoscopy, imaging, etc. is not routinely recommended as the diagnostic yield is low [126]. However, it should be performed without delay in atypical cases, for example, if renal calculi, outflow obstruction, interstitial cystitis or urothelial cancer is suspected.

Table 2: Age-related associations of rUTI in women [71, 101, 127]

Young and pre-menopausal women	Post-menopausal and elderly women
Sexual intercourse	History of UTI before menopause
Use of spermicide	Urinary incontinence
A new sexual partner	Atrophic vaginitis due to oestrogen deficiency
A mother with a history of UTI	Cystocele
History of UTI during childhood	Increased post-void urine volume
Blood group antigen secretory status	Blood group antigen secretory status
	Urine catheterisation and functional status
	deterioration in elderly institutionalised women

*3.5.3 **Disease management and follow-up***

Prevention of rUTIs includes counselling regarding avoidance of risk factors, non-antimicrobial measures and antimicrobial prophylaxis [125]. These interventions should be attempted in this order. Any urological risk factor must be identified and treated. Significant residual urine should be treated optimally, including by CIC when judged to be appropriate.

3.5.3.1 Behavioural modifications

A number of behavioural and personal hygiene measures (e.g. reduced fluid intake, habitual and post-coital delayed urination, wiping from front to back after defecation, douching and wearing occlusive underwear) have been suggested to decrease the risk of rUTI. However, studies that have explored underlying behavioural risk factors have consistently documented the lack of association with rUTI [125].

3.5.3.2 Non-antimicrobial prophylaxis

There are many non-antimicrobial measures recommended for rUTIs but only a few are supported by well-designed studies [128, 129].

3.5.3.2.1 Hormonal replacement

In post-menopausal women vaginal oestrogen replacement, but not oral oestrogen, showed a trend towards preventing rUTI [128, 130].

3.5.3.2.2 Immunoactive prophylaxis

OM-89 is sufficiently well documented and has been shown to be more effective than placebo in several randomised trials with a good safety profile. Therefore, it can be recommended for immunoprophylaxis in female patients with rUTIs [128, 131-133]. Efficacy in other groups of patients relative to antimicrobial prophylaxis remains to be established.

3.5.3.2.3 Prophylaxis with probiotics (Lactobacillus spp.)

Pooled data from a recent meta-analysis shows no convincing benefit of lactobacillus products as prophylaxis for rUTI [134]. However, differences in effectiveness between available preparations suggest further trials are needed before any definitive recommendation for or against their use can be made.

3.5.3.2.4 Prophylaxis with cranberry

Limited studies have suggested that cranberry is useful in reducing the rate of lower UTIs in women [135, 136]. However, a meta-analysis including 24 studies and comprising 4,473 participants showed that current

cranberry products did not significantly reduce the occurrence of symptomatic UTI for women with rUTI [137]. Due to these contradictory results, no recommendation on the daily consumption of cranberry products can be made.

3.5.3.2.5 Prophylaxis with D-mannose

In a randomised placebo-controlled non-blinded clinical trial, it was shown that a daily dose of 2 g D-mannose was significantly superior to placebo and as effective as 50 mg nitrofurantoin in preventing rUTI [138]. This is indicative but not sufficient for a recommendation; therefore, D-mannose should at present only be used within the context of clinical investigations.

3.5.3.2.6 Endovesical instillation

Endovesical instillations of hyaluronic acid and chondroitin sulphate have been used for glycosaminoglycan (GAG) layer replenishment in the treatment of interstitial cystitis, overactive bladder, radiation cystitis, and for prevention of rUTI [139]. A review of 27 clinical studies concluded that large-scale trials are urgently needed to assess the benefit of this type of therapy [140]; therefore, no general recommendation is possible at this stage.

3.5.3.3 Antimicrobials for preventing rUTI

3.5.3.3.1 Continuous low-dose antimicrobial prophylaxis and post-coital prophylaxis

Antimicrobials may be given as continuous low-dose prophylaxis for longer periods (three to six months), or as post-coital prophylaxis, as both regimens reduce the rate of rUTI [141]. It is mandatory to offer both options after counselling, and when behavioural modifications and non-antimicrobial measures have been unsuccessful. Regimens include nitrofurantoin 50 mg or 100 mg once daily, fosfomycin trometamol 3 g every ten days, trimethoprim 100 mg once daily and during pregnancy cephalexin 125 mg or 250 mg or cefaclor 250 mg once daily [125, 142]. Post-coital prophylaxis should be considered in pregnant women with a history of frequent UTIs before onset of pregnancy, to reduce their risk of UTI [143].

3.5.3.3.2 Self-diagnosis and self-treatment

In patients with good compliance, self-diagnosis and self-treatment with a short course regimen of an antimicrobial agent should be considered [144]. The choice of antimicrobials is the same as for sporadic acute uncomplicated UTI (section 3.4.4.4).

3.5.4 Summary of evidence and recommendations for the diagnostic evaluation and treatment of rUTIs

Summary of evidence	**LE**
Extensive routine workup including cystoscopy, imaging, etc. has a low diagnostic yield for the diagnosis of rUTI.	3
Studies that have investigated behavioural risk factors in the development of rUTIs have consistently documented the lack of association with rUTI.	3
Vaginal oestrogen replacement has shown a trend towards preventing rUTI in post-menopausal women.	1b
OM-89 has been shown to be more effective than placebo for immunoprophylaxis in female patients with rUTIs in several randomised trials with a good safety profile.	1a
Both continuous low-dose antimicrobial prophylaxis and post-coital antimicrobial prophylaxis, have been shown to reduce the rate of rUTI.	1b
A prospective cohort study showed that intermittent self-start therapy is effective, safe and economical in women with rUTIs.	2b

Recommendations	**Strength rating**
Diagnose recurrent UTI by urine culture.	Strong
Do not perform an extensive routine workup (e.g cystoscopy, full abdominal ultrasound) in women younger than 40 years of age with recurrent UTI and no risk factors.	Weak
Advise patients on behavioural modifications which might reduce the risk of recurrent UTI.	Weak
Use vaginal oestrogen replacement in post-menopausal women to prevent recurrent UTI.	Weak
Use immunoactive prophylaxis to reduce recurrent UTI in all age groups.	Strong
Use continuous or post-coital antimicrobial prophylaxis to prevent recurrent UTI when non-antimicrobial interventions have failed. Counsel patients regarding possible side effects.	Strong
For patients with good compliance self-administered short-term antimicrobial therapy should be considered.	Strong

3.6 Uncomplicated pyelonephritis

Uncomplicated pyelonephritis is defined as pyelonephritis limited to non-pregnant, pre-menopausal women with no known relevant urological abnormalities or comorbidities.

*3.6.1 **Diagnostic evaluation***

3.6.1.1 Clinical diagnosis

Pyelonephritis is suggested by fever (> 38°C), chills, flank pain, nausea, vomiting, or costovertebral angle tenderness, with or without the typical symptoms of cystitis [145]. Pregnant women with acute pyelonephritis need special attention, as this kind of infection may not only have an adverse effect on the mother with anaemia, renal and respiratory insufficiency, but also on the unborn child with more frequent preterm labour and birth [146].

3.6.1.2 Differential diagnosis

It is vital to differentiate as soon as possible between uncomplicated and complicated mostly obstructive pyelonephritis, as the latter can rapidly lead to urosepsis. This differential diagnosis should be made by the appropriate imaging technique (see section 3.6.1.4).

3.6.1.3 Laboratory diagnosis

Urinalysis including the assessment of white and red blood cells and nitrite, is recommended for routine diagnosis [147]. In addition, urine culture and antimicrobial susceptibility testing should be performed in all cases of pyelonephritis.

3.6.1.4 Imaging diagnosis

Evaluation of the upper urinary tract with ultrasound (US) should be performed to rule out urinary tract obstruction or renal stone disease in patients with a history of urolithiasis, renal function disturbances or a high urine pH [148]. Additional investigations, such as a contrast enhanced computed tomography (CT) scan, or excretory urography should be considered if the patient remains febrile after 72 hours of treatment, or immediately if there is deterioration in clinical status [148]. For diagnosis of complicating factors in pregnant women, US or magnetic resonance imaging (MRI) should be used preferentially to avoid radiation risk to the foetus [148].

*3.6.2 **Summary of evidence and recommendations for the diagnostic evaluation of uncomplicated pyelonephritis***

Summary of evidence	**LE**
Urine culture and antimicrobial susceptibility testing should be performed in all cases of pyelonephritis in addition to urinalysis.	4
A prospective observational cohort study found that radiologic imaging can selectively be applied in adults with febrile UTI without loss of clinically relevant information by using a simple clinical prediction rule.	2b
Additional imaging investigations, such as an unenhanced helical computed tomography should be done if the patient remains febrile after 72 hours of treatment or in patients with suspected complications e.g. sepsis.	4

Recommendations	**Strength rating**
Perform urinalysis (e.g. using the dipstick method), including the assessment of white and red blood cells and nitrite, for routine diagnosis.	Strong
Perform urine culture and antimicrobial susceptibility testing in patients with pyelonephritis.	Strong
Perform imaging of the urinary tract to exclude urgent urological disorders.	Strong

*3.6.3 **Disease management***

3.6.3.1 Outpatient treatment

Fluoroquinolones and cephalosporines are the only antimicrobial agents that can be recommended for oral empirical treatment of uncomplicated pyelonephritis [149]. However, oral cephalosporines achieve significantly lower blood and urinary concentrations than intravenous cephalosporines. Other agents such as nitrofurantoin, oral fosfomycin, and pivmecillinam should be avoided as there is insufficient data regarding their efficacy [150]. In the setting of fluoroquinolone hypersensitivity or known resistance, other acceptable choices include trimethoprim-sulfamethoxazole (160/800 mg) or an oral beta-lactam, if the uropathogen is known to be

susceptible. If such agents are used in the absence of antimicrobial susceptibility results, an initial intravenous dose of a long-acting parenteral antimicrobial (e.g. ceftriaxone) should be administered. A short outpatient antibiotic course of treatment, for acute pyelonephritis, has been shown to be equivalent to longer durations of therapy in terms of clinical and microbiological success. However, this is associated with a higher recurrence rate of infection within four to six weeks and needs to be tailored to local policies and resistance patterns [151].

3.6.3.2 Inpatient treatment

Patients with uncomplicated pyelonephritis requiring hospitalisation should be treated initially with an intravenous antimicrobial regimen e.g. a fluoroquinolone, an aminoglycoside (with or without ampicillin), or an extended-spectrum cephalosporin or penicillin [152]. Ceftolozane/tazobactam achieved a clinical response rate of over 90% in patients with uncomplicated pyelonephritis [153, 154]. It also demonstrated significantly higher composite cure rates than levofloxacin among levofloxacin-resistant pathogens [155]. Ceftazidime-avibactam combination has been shown to be effective for treating ceftazidime-resistant Enterobacteriaceae and *Pseudomonas aeruginosa* UTIs [156].

Novel antimicrobial agents include imipenem/cilastatin, cefiderocol, meropenem-vaborbactam and plazomicin. Imipenem/cilastatin has been investigated in a phase 2 randomised trial and showed good clinical response rates [157]. Cefatazidime-avibactam and doripenem showed similar efficacy against ceftazidime non-susceptible pathogens and may offer an alternative to carbapenems in this setting [158]. Meropenem-vaborbactam has been shown to be non-inferior to piperacillin-tazobactam in a phase 3 RCT [159]. It was also effective for treating carbapenem-resistant Enterobacteriaceae with cure rates of 65% compared to best available treatment [160]. Once daily plazomicin was non-inferior to meropenem for the treatment of cUTIs and acute pyelonephritis caused by Enterobacteriaceae, including multidrug-resistant strains [161]. Cefiderocol was non-inferior to imipenem/cilastatin for the treatment of complicated UTI in people with multidrug-resistant Gram-negative infections in a phase 2 RCT [162].

Carbapenems and novel broad spectrum antimicrobial agents should only be considered in patients with early culture results indicating the presence of multi-drug resistant organisms. The choice between these agents should be based on local resistance patterns and optimised on the basis of drug susceptibility results. In patients presenting with signs of urosepsis empiric antimicrobial coverage for ESBL-producing organisms is warranted [163]. Patients initially treated with parenteral therapy who improve clinically and can tolerate oral fluids may transition to oral antimicrobial therapy [164].

3.6.3.2.1 Summary of evidence and recommendations for the treatment of uncomplicated pyelonephritis

Summary of evidence	**LE**
Fluoroquinolones and cephalosporines are the only microbial agents that can be recommended for oral empirical treatment of uncomplicated pyelonephritis.	1b
Intravenous antimicrobial regimens for uncomplicated pyelonephritis may include a fluoroquinolone, an aminoglycoside (with or without ampicillin), or an extended-spectrum cephalosporin or penicillin.	1b
Carbapenems should only be considered in patients with early culture results indicating the presence of multi-drug resistant organisms.	4
The appropriate antimicrobial should be chosen based on local resistance patterns and optimised on the basis of drug susceptibility results.	3

Recommendations	**Strength rating**
Treat patients with uncomplicated pyelonephritis not requiring hospitalisation with short course fluoroquinolones as first-line treatment.	Strong
Treat patients with uncomplicated pyelonephritis requiring hospitalisation with an intravenous antimicrobial regimen initially.	Strong
Switch patients initially treated with parenteral therapy, who improve clinically and can tolerate oral fluids, to oral antimicrobial therapy.	Strong
Do not use nitrofurantoin, oral fosfomycin, and pivmecillinam to treat uncomplicated pyelonephritis.	Strong

Table 3: Suggested regimens for empirical oral antimicrobial therapy in uncomplicated pyelonephritis

Antimicrobial	Daily dose	Duration of therapy	Comments
Ciprofloxacin	500-750 mg b.i.d	7 days	Fluoroquinolone resistance should be less than 10%.
Levofloxacin	750 mg q.d	5 days	
Trimethoprim sulfamethoxazol	160/800 mg b.i.d	14 days	If such agents are used empirically, an initial intravenous dose of a long-acting parenteral antimicrobial (e.g. ceftriaxone) should be administered.
Cefpodoxime	200 mg b.i.d	10 days	
Ceftibuten	400 mg q.d	10 days	

b.i.d = twice daily; q.d = every day.

Table 4: Suggested regimens for empirical parenteral antimicrobial therapy in uncomplicated pyelonephritis

Antimicrobials	Daily dose	Comments
First-line treatment		
Ciprofloxacin	400 mg b.i.d	
Levofloxacin	750 mg q.d	
Cefotaxime	2 g t.i.d	Not studied as monotherapy in acute uncomplicated pyelonephritis.
Ceftriaxone	1-2 g q.d	Lower dose studied, but higher dose recommended.
Second-line treatment		
Cefepime	1-2 g b.i.d	Lower dose studied, but higher dose recommended.
Piperacillin/tazobactam	2.5-4.5 g t.i.d	
Gentamicin	5 mg/kg q.d	Not studied as monotherapy in acute uncomplicated pyelonephritis.
Amikacin	15 mg/kg q.d	
Last-line alternatives		
Imipenem/cilastatin	0.5 g t.i.d	Consider carbapenems only in patients with early culture results indicating the presence of multi-drug resistant organisms.
Meropenem	1 g t.i.d	
Ceftolozane/tazobactam	1.5 g t.i.d	
Ceftazidime/avibactam	2.5 g t.i.d	
Cefiderocol	2g t.i.d	
Meropenem-vaborbactam	2g t.i.d	
Plazomicin	15mg/kg o.d	

b.i.d = twice daily; t.i.d = three times daily; q.d = every day; o.d = once daily.

In pregnant women with pyelonephritis, outpatient management with appropriate parenteral antimicrobials may also be considered, provided symptoms are mild and close follow-up is feasible [165, 166]. In more severe cases of pyelonephritis, hospitalisation and supportive care are usually required. After clinical improvement parenteral therapy can also be switched to oral therapy for a total treatment duration of seven to ten days. In men with febrile UTI, pyelonephritis, or recurrent infection, or whenever a complicating factor is suspected a minimum treatment duration of two weeks is recommended, preferably with a fluoroquinolone since prostatic involvement is frequent [167].

*3.6.4 **Follow-up***

Post-treatment urinalysis or urine cultures in asymptomatic patients post-therapy are not indicated.

3.7 Complicated UTIs

*3.7.1 **Introduction***

A complicated UTI (cUTI) occurs in an individual in whom factors related to the host (e.g. underlying diabetes or immunosuppression) or specific anatomical or functional abnormalities related to the urinary tract (e.g. obstruction, incomplete voiding due to detrusor muscle dysfunction) are believed to result in an infection that will be more difficult to eradicate than an uncomplicated infection [168-170]. New insights into the management of cUTIs also suggest to consider infections caused by multi-drug resistant uropathogens [171]. The underlying factors that are generally accepted to result in a cUTI are outlined in Table 5. The designation of cUTI encompasses a wide variety of underlying conditions that result in a remarkably heterogeneous patient population. Therefore, it is readily apparent that a universal approach to the evaluation and treatment of cUTIs

is not sufficient, although there are general principles of management that can be applied to the majority of patients with cUTIs. The following recommendations are based on the Stichting Werkgroep Antibioticabeleid (SWAB) Guidelines from the Dutch Working Party on Antibiotic Policy [172].

Table 5: Common factors associated with complicated UTIs [171-174]

Obstruction at any site in the urinary tract	UTI in males
Foreign body	Pregnancy
Incomplete voiding	Diabetes mellitus
Vesicoureteral reflux	Immunosuppression
Recent history of instrumentation	Healthcare-associated infections
Isolated ESBL-producing organisms	Isolated multi-drug resistant organisms

*3.7.2 **Diagnostic evaluation***

3.7.2.1 Clinical presentation

A cUTI is associated with clinical symptoms (e.g. dysuria, urgency, frequency, flank pain, costovertebral angle tenderness, suprapubic pain and fever), although in some clinical situations the symptoms may be atypical for example, in neuropathic bladder disturbances, CA-UTI or patients who have undergone radical cystectomy with urinary diversion. In addition, all patients with nephrostomy may have an atypical clinical presentation. Clinical presentation can vary from severe obstructive acute pyelonephritis with imminent urosepsis to a post-operative CA-UTI, which might disappear spontaneously as soon as the catheter is removed. Clinicians must also recognise that symptoms, especially lower urinary tract symptoms (LUTS), are not only caused by UTIs but also by other urological disorders, such as, for example, benign prostatic hyperplasia and autonomic dysfunction in patients with spinal lesions and neurogenic bladders. Concomitant medical conditions, such as diabetes mellitus and renal failure, which can be related to urological abnormalities, are often also present in a cUTI.

3.7.2.2 Urine culture

Laboratory urine culture is the recommended method to determine the presence or absence of clinically significant bacteriuria in patients suspected of having a cUTI.

*3.7.3 **Microbiology (spectrum and antimicrobial resistance)***

A broad range of micro-organisms cause cUTIs. The spectrum is much larger than in uncomplicated UTIs and the bacteria are more likely to be resistant (especially in treatment-related cUTI) than those isolated in uncomplicated UTIs [173, 174]. *E. coli*, *Proteus* spp., *Klebsiella* spp., *Pseudomonas* spp., *Serratia* spp. and *Enterococcus* spp. are the most common species found in cultures. Enterobacteriaceae predominate (60-75%), with *E. coli* as the most common pathogen; particularly if the UTI is a first infection. Otherwise, the bacterial spectrum may vary over time and from one hospital to another [175].

*3.7.4 **General principles of cUTI treatment***

Appropriate management of the urological abnormality or the underlying complicating factor is mandatory. Optimal antimicrobial therapy for cUTI depends on the severity of illness at presentation, as well as local resistance patterns and specific host factors (such as allergies). In addition, urine culture and susceptibility testing should be performed, and initial empirical therapy should be tailored and followed by (oral) administration of an appropriate antimicrobial agent on the basis of the isolated uropathogen.

3.7.4.1 Choice of antimicrobials

Considering the current resistance percentages of amoxicillin, co-amoxiclav, trimethoprim and trimethoprim-sulphamethoxazole, it can be concluded that these agents are not suitable for the empirical treatment of pyelonephritis in a normal host and, therefore, also not for treatment of all cUTIs [176]. The same applies to ciprofloxacin and other fluoroquinolones in urological patients [176].

Patients with a UTI with systemic symptoms requiring hospitalisation should be initially treated with an intravenous antimicrobial regimen, such as an aminoglycoside with or without amoxicillin, or a second or third generation cephalosporin, or an extended-spectrum penicillin with or without an aminoglycoside [172]. The choice between these agents should be based on local resistance data, and the regimen should be tailored on the basis of susceptibility results [150]. These recommendations are not only suitable for pyelonephritis, but for all other cUTIs.

Alternative regimens for the treatment of cUTIs, particularly those caused by multidrug-resistant pathogens have been studied. Ceftolozane/tazobactam 1.5 g every eight hours demonstrated high clinical

cure rates for cUTIs caused by ESBL-producing Enterobacteriaceae in a pooled analysis of phase 3 clinical trials [177]. Cefiderocol (2 g) three times daily was non-inferior to imipenem-cilastatin (1 g) three times daily for the treatment of cUTI in patients with multidrug-resistant Gram-negative infections [162]. Imipenem/cilastatin plus relebactam (250 or 125 mg) was as effective as imipenem/cilastatin alone for treatment of cUTI in a phase 2 RCT [157]. Ceftazidime/avibactam has been shown to be as effective as carbapenems for the treatment of cUTI in a systematic review reporting a baseline of 25% for ESBL-producing Enterobacteriaceae, but more severe adverse events were reported in the ceftazidime/avibactam group [178]. Once-daily plazomicin was shown to be non-inferior to meropenem for the treatment of cUTIs caused by Enterobacteriaceae, including multidrug-resistant strains [161].

In view of the high degree of resistance, particularly among patients admitted to the department of urology, fluoroquinolones are not automatically suitable as empirical antimicrobial therapy, especially when the patient has used ciprofloxacin in the last six months [179]. Fluoroquinolones can only be recommended as empirical treatment when the patient is not seriously ill and it is considered safe to start initial oral treatment or if the patient has had an anaphylactic reaction to beta-lactam antimicrobials. Intravenous levofloxacin 750 mg once daily for five days has been shown to be non-inferior to a seven to fourteen day regimen of levofloxacin 500 mg once daily starting intravenously and switched to an oral regimen (based on mitigation of clinical symptoms) [180].

3.7.4.2 Duration of antimicrobial therapy

Treatment for seven [181] to fourteen days (for men fourteen days when prostatitis cannot be excluded) [182] is generally recommended, but the duration should be closely related to the treatment of the underlying abnormality. When the patient is hemodynamically stable and afebrile for at least 48 hours, a shorter treatment duration (e.g. seven days) may be considered in patients where a short-course treatment is desired due to relative-contraindications to the administered antibiotic [180].

*3.7.5 **Summary of evidence and recommendations for the treatment of complicated UTIs***

Summary of evidence	**LE**
Patients with a UTI with systemic symptoms requiring hospitalisation should be initially treated with an intravenous antimicrobial regimen chosen based on local resistance data and previous urine culture results from the patient, if available. The regimen should be tailored on the basis of susceptibility result.	1b
If the prevalence of fluoroquinolone resistance is thought to be < 10% and the patient has contraindications for third generation cephalosporins or an aminoglycoside, ciprofloxacin can be prescribed as an empirical treatment in women with complicated pyelonephritis.	2
In the event of hypersensitivity to penicillin a cephalosporins can still be prescribed, unless the patient has had systemic anaphylaxis in the past.	2
In patients with a cUTI with systemic symptoms, empirical treatment should cover ESBL-producing organisms if there is an increased likelihood of ESBL infection based on prevalence in the community, earlier collected cultures and prior antimicrobial exposure of the patient.	2
Intravenous levofloxacin 750 mg once daily for five days, is non-inferior to a seven to fourteen day regimen of levofloxacin 500 mg once daily starting intravenously and switched to an oral regimen (based on mitigation of clinical symptoms).	2

Recommendations	**Strength rating**
Use the combination of: • amoxicillin plus an aminoglycoside; • a second generation cephalosporin plus an aminoglycoside; • a third generation cephalosporin intravenously as empirical treatment of complicated UTI with systemic symptoms.	Strong
Only use ciprofloxacin provided that the local resistance percentages are < 10% when; • the entire treatment is given orally; • patients do not require hospitalisation; • patient has an anaphylaxis for beta-lactam antimicrobials.	Strong
Do not use ciprofloxacin and other fluoroquinolones for the empirical treatment of complicated UTI in patients from urology departments or when patients have used fluoroquinolones in the last six months.	Strong
Manage any urological abnormality and/or underlying complicating factors.	Strong

3.8 Catheter-associated UTIs

*3.8.1 **Introduction***

Catheter-associated UTI refers to UTIs occurring in a person whose urinary tract is currently catheterised or has been catheterised within the past 48 hours. The urinary catheter literature is problematic as many published studies use the term CA-bacteriuria without providing information on what proportion are CA-ABU and CA-UTI, and some studies use the term CA-UTI when referring to CA-ABU or CA-bacteriuria [173]. The following recommendations are based on the SWAB Guidelines from the Dutch Working Party on Antibiotic Policy [172] as well as the IDSA Guidelines [173].

*3.8.2 **Epidemiology, aetiology and pathophysiology***

Catheter-associated UTIs are the leading cause of secondary healthcare-associated bacteraemia. Approximately 20% of hospital-acquired bacteraemias arise from the urinary tract, and the mortality associated with this condition is approximately 10% [183]. The incidence of bacteriuria associated with indwelling catheterisation is 3-8% per day [184-188]. The duration of catheterisation is the most important risk factor for the development of a CA-UTI [189, 190]. Urinary catheterisation perturbs host defence mechanisms and provides easier access of uropathogens to the bladder. Indwelling urinary catheters facilitate colonisation with uropathogens by providing a surface for the attachment of host cell binding receptors recognised by bacterial adhesins, thus enhancing microbial adhesion. In addition, the uroepithelial mucosa is disrupted, exposing new binding sites for bacterial adhesins, and residual urine in the bladder is increased through pooling below the catheter bulb [191]. Catheter-associated UTIs are often polymicrobial and caused by multiple-drug resistant uropathogens.

*3.8.3 **Diagnostic evaluation***

3.8.3.1 Clinical diagnosis

Signs and symptoms compatible with CA-UTI include new onset or worsening of fever, rigors, altered mental status, malaise, or lethargy with no other identified cause, flank pain, costovertebral angle tenderness, acute haematuria, pelvic discomfort and in those whose catheters have been removed dysuria, urgent or frequent urination and suprapubic pain or tenderness [172]. In the catheterised patient, the presence or absence of odorous or cloudy urine alone should not be used to differentiate CA-ABU from CA-UTI [172, 173].

3.8.3.2 Laboratory diagnosis

Microbiologically, CA-UTI is defined by microbial growth of ≥ 10^3 cfu/mL of one or more bacterial species in a single catheter urine specimen or in a mid-stream voided urine specimen from a patient whose urethral, suprapubic, or condom catheter has been removed within the previous 48 hours. In catheterised patients, pyuria is not diagnostic for CA-UTI. The presence, absence, or degree of pyuria should not be used to differentiate CA-ABU from CA-UTI. Pyuria accompanying CA-ABU should not be interpreted as an indication for antimicrobial treatment. The absence of pyuria in a symptomatic patient suggests a diagnosis other than CA-UTI [173].

3.8.3.3 Summary of evidence table and recommendations for diagnostic evaluation of CA-UTI

Summary of evidence	**LE**
Patients with indwelling or suprapubic catheters become carriers of ABU, with antibiotic treatment showing no benefit.	1a
In the catheterised patient, the presence or absence of odorous or cloudy urine alone should not be used to differentiate CA-ABU from CA-UTI.	2
Microbiologically CA-UTI is defined by microbial growth of ≥ 10^3 cfu/mL of one or more bacterial species in a single catheter urine specimen or in a mid-stream voided urine specimen from a patient whose catheter has been removed within the previous 48 hours.	3

Recommendations	**Strength rating**
Do not carry out routine urine culture in asymptomatic catheterised patients.	Strong
Do not use pyuria as sole indicator for catheter-associated UTI.	Strong
Do not use the presence or absence of odorous or cloudy urine alone to differentiate catheter-associated asymptomatic bacteriuria from catheter-associated UTI.	Strong

3.8.4 *Disease management*

A urine specimen for culture should be obtained prior to initiating antimicrobial therapy for presumed CA-UTI due to the wide spectrum of potential infecting organisms and the increased likelihood of antimicrobial resistance. The urine culture should be obtained from the freshly placed catheter prior to the initiation of antimicrobial therapy [173]. Based on the global prevalence on infections in urology (GPIU) study, the causative micro-organisms in CA-UTI are comparable with the causative micro-organisms in other cUTIs; therefore, symptomatic CA-UTIs should be treated according to the recommendations for cUTI (see section 3.7.5) [192].

Seven days is the recommended duration of antimicrobial treatment for patients with CA-UTI who have prompt resolution of symptoms, and fourteen days of treatment is recommended for those with a delayed response, regardless of whether the patient remains catheterised or not [173]. A five-day regimen of levofloxacin may be considered in patients with CA-UTI who are not severely ill. Data are insufficient to make such a recommendation about other fluoroquinolones.

A three-day antimicrobial regimen may be considered for women aged ≤ 65 years who develop CA-UTI without upper urinary tract symptoms after an indwelling catheter has been removed. If an indwelling catheter has been in place for two weeks at the onset of CA-UTI and is still indicated, the catheter should be replaced to hasten resolution of symptoms and to reduce the risk of subsequent CA-bacteriuria and CA-UTI. If use of the catheter can be discontinued, a culture of a voided mid-stream urine specimen should be obtained prior to the initiation of antimicrobial therapy to help guide treatment [173]. Long-term indwelling catheters should not be changed routinely. Follow appropriate practices for catheter insertion and care [193].

3.8.4.1 *Recommendations for disease management and prevention of CA-UTI*

Recommendations	Strength rating
Treat symptomatic catheter-associated UTI according to the recommendations for complicated UTI (see section 3.7.5).	Strong
Take a urine culture prior to initiating antimicrobial therapy in catheterised patients in whom the catheter has been removed.	Strong
Do not treat catheter-associated asymptomatic bacteriuria in general.	Strong
Treat catheter-associated asymptomatic bacteriuria prior to traumatic urinary tract interventions (e.g. transurethral resection of the prostate).	Strong
Replace or remove the indwelling catheter before starting antimicrobial therapy.	Strong
Do not apply topical antiseptics or antimicrobials to the catheter, urethra or meatus.	Strong
Do not use prophylactic antimicrobials to prevent catheter-associated UTIs.	Strong
The duration of catheterisation should be minimal.	Strong

3.8.5 *Removal of indwelling bladder catheter*

3.8.5.1 *Evidence question*

1. Does antibiotic prophylaxis reduce the rate of symptomatic UTI in adults following indwelling bladder catheter removal?

3.8.5.2 *Review of evidence*

A structured literature search identified one systematic review and meta-analysis [194] with a search date of November 2012 and one subsequent RCT [195]. Marschall *et al.*, identified seven RCTs with 1,520 participants. Meta-analysis showed overall benefit for use of prophylaxis RR (95%CI) = 0.45 (0.28-0.72); ARR 5.8% (from 10.5% to 4.7%) with a number needed to treat (NNT) of 17. Results for individual trials were inconsistent with five trials including the possibility of no benefit [194]. The trial reported by Fang *et al.*, recruited 172 participants undergoing laparoscopic radical prostatectomy randomised to seven days of ciprofloxacin (n=80) or no treatment (n=80). At the time of catheter removal which, occurred at a mean of nine days post-operatively, there was no difference in infective complications recorded at up to four weeks after catheter removal. More isolates obtained from the prophylaxis group (11) were resistant to ciprofloxacin compared to the no treatment group (3) [195].

3.8.5.3 Summary of evidence and recommendations for diagnostic evaluation of CA-UTI

Summary of evidence	LE
A meta-analysis showed overall benefit for use of prophylaxis for reduction of infective complications after catheter removal; however, results from individual trials were inconsistent with five out of seven trials including the possibility of no benefit.	1a
A subsequent RCT found no benefit of antibiotic prophylaxis for reduction of infective complications at up to four weeks after catheter removal.	1b

Recommendation	Strength rating
Do not routinely use antibiotic prophylaxis to prevent clinical UTI after urethral catheter removal.	Weak

3.9 Urosepsis

*3.9.1 **Introduction***

Patients with urosepsis should be diagnosed at an early stage, especially in the case of a cUTI. Systemic inflammatory response syndrome (SIRS), characterised by fever or hypothermia, leukocytosis or leukopenia, tachycardia and tachypnoea, has been recognised as a set of alerting symptoms [196, 197]; however, SIRS is no longer included in the recent terminology of sepsis (Table 6) [12]. Mortality is considerably increased the more severe the sepsis is.

The treatment of urosepsis involves adequate life-supporting care, appropriate and prompt antimicrobial therapy, adjunctive measures and the optimal management of urinary tract disorders [198]. Source control by decompression of any obstruction and drainage of larger abscesses in the urinary tract is essential [198]. Urologists are recommended to treat patients in collaboration with intensive care and infectious diseases specialists.

Urosepsis is seen in both community-acquired and healthcare associated infections. Nosocomial urosepsis may be reduced by measures used to prevent nosocomial infection, e.g. reduction of hospital stay, early removal of indwelling urinary catheters, avoidance of unnecessary urethral catheterisation, correct use of closed catheter systems, and attention to simple daily aseptic techniques to avoid cross-infection.

Sepsis is diagnosed when clinical evidence of infection is accompanied by signs of systemic inflammation, presence of symptoms of organ dysfunction and persistent hypotension associated with tissue anoxia (Table 6).

*3.9.2 **Epidemiology, aetiology and pathophysiology***

Urinary tract infections can manifest from bacteriuria with limited clinical symptoms to sepsis or severe sepsis, depending on localised and potential systemic extension. It is important to note that a patient can move from an almost harmless state to severe sepsis in a very short time.

Mortality rates associated with sepsis vary depending on the organ source [199] with urinary tract sepsis generally having a lower mortality than that from other sources [200]. Sepsis is more common in men than in women [201]. In recent years, the overall incidence of sepsis arising from all sources has increased by 8.7% per year [199], but the associated mortality has decreased, which suggests improved management of patients (total in-hospital mortality rate fell from 27.8% to 17.9% from 1995 to 2000) [202]. Although the rate of sepsis due to Gram-positive and fungal organisms has increased, Gram-negative bacteria remain predominant in urosepsis [192, 203].

In urosepsis, as in other types of sepsis, the severity depends mostly upon the host response.
Patients who are more likely to develop urosepsis include elderly patients, diabetics, immunosuppressed patients, such as transplant recipients and patients receiving cancer chemotherapy or corticosteroids. Urosepsis also depends on local factors, such as urinary tract calculi, obstruction at any level in the urinary tract, congenital uropathy, neurogenic bladder disorders, or endoscopic manoeuvres. However, all patients can be affected by bacterial species that are capable of inducing inflammation within the urinary tract.

*3.9.3 **Diagnostic evaluation***

For diagnosis of systemic symptoms in sepsis either the full Sequential [Sepsis-related] Organ Failure Assessment (SOFA) score, or the quickSOFA score should be applied (Table 6). Microbiology sampling should be applied to urine, two sets of blood cultures [204], and if appropriate drainage fluids. Imaging investigations, such as sonography and CT-scan should be performed early [205].

Table 6. Definition and criteria of sepsis and septic shock [12, 196, 197]

Disorder	Definition
Sepsis	Life-threatening organ dysfunction caused by a dysregulated host response to infection. For clinical application, organ dysfunction can be represented by an increase in the Sequential [Sepsis-related] Organ Failure Assessment (SOFA) score of 2 points or more. For rapid identification a quickSOFA (qSOFA) score was developed: respiratory rate of 22/min or greater, altered mentation, or systolic blood pressure of 100 mmHg or less.
Septic shock	Septic shock should be defined as a subset of sepsis in which particularly profound circulatory, cellular, and metabolic abnormalities are associated with a greater risk of mortality than with sepsis alone. Patients with septic shock can be clinically identified by a vasopressor requirement to maintain a mean arterial pressure of 65 mm Hg or greater and serum lactate level greater than 2 mmol/L (>18 mg/dL) in the absence of hypovolemia.

3.9.4 ***Physiology and biochemical markers***

E. coli remains the most prevalent micro-organism. In several countries, bacterial strains can be resistant or multi-resistant and therefore difficult to treat [203]. Most commonly, the condition develops in compromised patients (e.g. those with diabetes or immunosuppression), with typical signs of generalised sepsis associated with local signs of infection.

3.9.4.1 Cytokines as markers of the septic response

Cytokines are involved in the pathogenesis of sepsis [200]. They are molecules that regulate the amplitude and duration of the host inflammatory response. They are released from various cells including monocytes, macrophages and endothelial cells, in response to various infectious stimuli. The complex balance between pro- and anti-inflammatory responses is modified in severe sepsis. An immunosuppressive phase follows the initial pro-inflammatory mechanism. Sepsis may indicate an immune system that is severely compromised and unable to eradicate pathogens or a non-regulated and excessive activation of inflammation, or both. Genetic predisposition is a probable explanation of sepsis in several patients. Mechanisms of organ failure and death in patients with sepsis remain only partially understood [200].

3.9.4.2 Biochemical markers

Procalcitonin is the inactive pro-peptide of calcitonin. Normally, levels are undetectable in healthy humans. During severe generalised infections (bacterial, parasitic and fungal) with systemic manifestations, procalcitonin levels rise [206]. In contrast, during severe viral infections or inflammatory reactions of non-infectious origin, procalcitonin levels show only a moderate or no increase. Mid-regional proadrenomedulline is another sepsis marker. Mid-regional proadrenomedullin has been shown to play a decisive role in the induction of hyperdynamic circulation during the early stages of sepsis and progression to septic shock [207]. Procalcitonin monitoring may be useful in patients likely to develop sepsis and to differentiate from a severe inflammatory status not due to bacterial infection [206, 208]. In addition, serum lactate is a marker of organ dysfunction and is associated with mortality in sepsis [209]. Serum lactate should therefore also be monitored in patients with severe infections.

3.9.5 ***Disease management***

3.9.5.1 Prevention

Septic shock is the most frequent cause of death for patients hospitalised for community-acquired and nosocomial infection (20-40%). Urosepsis treatment requires a combination of treatment including source control (obstruction of the urinary tract), adequate life-support care, and appropriate antimicrobial therapy [200, 205]. In such a situation, it is recommended that urologists collaborate with intensive care and infectious disease specialists for the best management of the patient.

3.9.5.1.1 Preventive measures of proven or probable efficacy

The most effective methods to prevent nosocomial urosepsis are the same as those used to prevent other nosocomial infections [210, 211] they include:

- Isolation of patients with multi-resistant organisms following local and national recommendations.
- Prudent use of antimicrobial agents for prophylaxis and treatment of established infections, to avoid selection of resistant strains. Antibiotic agents should be chosen according to the predominant pathogens at a given site of infection in the hospital environment.
- Reduction in hospital stay. Long inpatient periods before surgery lead to a greater incidence of nosocomial infections.
- Early removal of indwelling urethral catheters, as soon as allowed by the patient's condition. Nosocomial UTIs are promoted by bladder catheterisation as well as by ureteral stenting [212]. Antibiotic prophylaxis does not prevent stent colonisation, which appears in 100% of patients with a permanent ureteral stent and in 70% of those temporarily stented.
- Use of closed catheter drainage and minimisation of breaks in the integrity of the system, e.g. for urine sampling or bladder wash-out.
- Use of least-invasive methods to release urinary tract obstruction until the patient is stabilised.
- Attention to simple everyday techniques to assure asepsis, including the routine use of protective disposable gloves, frequent hand disinfection, and using infectious disease control measures to prevent cross-infections.

3.9.5.1.2 Appropriate peri-operative antimicrobial prophylaxis

For appropriate peri-operative antimicrobial prophylaxis see section 3.15. The potential side effects of antibiotics must be considered before their administration in a prophylactic regimen.

3.9.5.2 Treatment

Early goal-directed resuscitation was initially shown to improve survival for emergency department patients presenting with septic shock in a randomised, controlled, single-centre study [213]. However, follow-up studies in an improved emergency medicine background have not achieved positive effects with this strategy [214-216]. An individual patient data meta-analysis of the later three multicentre trials concluded that early goal-directed therapy did not result in better outcomes than usual care and was associated with higher hospitalisation costs [217].

3.9.5.2.1 Antimicrobial therapy

Initial empiric antimicrobial therapy should provide broad antimicrobial coverage against all likely causative pathogens and should be adapted on the basis of culture results, once available [198, 205]. The dosage of the antimicrobial substances is of paramount importance in patients with sepsis syndrome and should generally be high, with appropriate adjustment for renal function [198]. Antimicrobials must be administered no later than one hour after clinical assumption of sepsis [198].

3.9.5.2.2 Source control

Obstruction in the urinary tract is the most frequent urological source of urosepsis. Drainage of obstruction and abscesses, and removal of foreign bodies, such as urinary catheters or stones is therefore the most important source control strategy. These are key components of the strategy. This condition is an absolute emergency.

3.9.5.2.3 Adjunctive measures

The most important adjunctive measures in the management of sepsis are the following [198, 205]:

- fluid therapy with crystalloids, or albumin, if crystalloids are not adequately increasing blood pressure: passive leg raising-induced changes in cardiac output and in arterial pulse pressure are predictors of fluid responsiveness in adults [218];
- as vasopressors norepinephrine should be used primarily, dobutamine in myocardial dysfunction;
- hydrocortisone should be given only if fluid and vasopressors do not achieve a mean arterial pressure of ≥ 65 mmHg;
- blood products should be given to target a haemoglobin level of 7-9 g/dL;
- mechanical ventilation should be applied with a tidal volume 6 mL/kg and plateau pressure ≤ 30 cm H_2O and a high positive end-expiratory pressure;
- sedation should be given minimally, neuromuscular blocking agents should be avoided;
- glucose levels should be target at ≤ 180 mg/dL;
- deep vein thrombosis prevention should be given with low-molecular weight heparin subcutaneously;
- stress ulcer prophylaxis should be applied in patients at risk, using protone pump inhibitors;
- enteral nutrition should be started early (< 48 hours).

In conclusion, sepsis in urology remains a severe situation with a considerable mortality rate. A recent campaign, 'Surviving Sepsis Guidelines', aims to reduce mortality by 25% in the next years [198, 205, 219]. Early recognition of the symptoms may decrease the mortality by timely treatment of urinary tract disorders, e.g. obstruction, or urolithiasis. Adequate life-support measures and appropriate antimicrobial treatment provide the best conditions for improving patient survival. The prevention of sepsis is dependent on good practice to avoid nosocomial infections and using antimicrobial prophylaxis and therapy in a prudent and well-accepted manner.

3.9.5.3 Summary of evidence and recommendations for the diagnosis and treatment of urosepsis

Summary of evidence	LE
Initial high dose empiric antimicrobial therapy, administered within the first hour, should provide broad antimicrobial coverage against all likely causative pathogens and should be adapted on the basis of culture results, once available.	2b
Source control interventions should be implemented as soon as possible to control or eliminate diagnosed and/or suspected infectious foci.	3

Recommendations	Strength rating
Perform the quickSOFA score to identify patients with potential sepsis.	Strong
Take a urine culture and two sets of blood cultures before starting antimicrobial treatment.	Strong
Administer parenteral high dose broad spectrum antimicrobials within the first hour after clinical assumption of sepsis.	Strong
Adapt initial empiric antimicrobial therapy on the basis of culture results.	Strong
Initiate source control including removal of foreign bodies, decompression of obstruction and drainage of abscesses in the urinary tract.	Strong
Provide immediate adequate life-support measures.	Strong

Table 7: Suggested regimens for antimicrobial therapy for urosepsis.

Antimicrobials	Daily dose	Duration of therapy
Cefotaxime	2 g t.i.d	7-10 days Longer courses are appropriate in patients who have a slow clinical response
Ceftazidime	1-2 g t.i.d	
Ceftriaxone	1-2 g q.d	
Cefepime	2 g b.i.d	
Piperacillin/tazobactam	4.5 g t.i.d	
Ceftolozane/tazobactam	1.5 g t.i.d	
Ceftazidime/avibactam	2.5 g t.i.d	
Gentamicin*	5 mg/kg q.d	
Amikacin*	15 mg/kg q.d	
Ertapenem	1 g q.d	
Imipenem/cilastatin	0.5 g t.i.d	
Meropenem	1 g t.i.d	

** Not studied as monotherapy in urosepsis*
b.i.d = twice daily; t.i.d = three times daily; q.d = every day.

3.10 Urethritis

*3.10.1 **Introduction***

Urethritis can be of either infectious or non-infectious origin. Inflammation of the urethra presents usually with LUTS and must be distinguished from other infections of the lower urinary tract. Urethral infection is typically spread by sexual contact.

*3.10.2 **Epidemiology, aetiology and pathogenesis***

From a therapeutic and clinical point of view, gonorrhoeal urethritis (GU) caused by *Neisseria gonorrhoeae* must be differentiated from non-gonococcal urethritis (NGU). Non-gonococcal urethritis is a non-specific diagnosis that can have many infectious aetiologies. Causative pathogens include *Chlamydia trachomatis*, *Mycoplasma genitalium*, *Ureaplasma urealyticum* and *Trichomonas vaginalis*. The role of *Ureaplasma* spp. as urethritis

causative pathogens is controversial. Recent data suggests that *U. urealyticum*, but not *U. parvum* is an aetiological agent in NGU [220]. The prevalence of isolated causative pathogens are: *C. trachomatis* 11-50%; *M. genitalium* 6-50%; Ureaplasmas 5-26%; *T. vaginalis* 1-20%; and adenoviruses 2-4% [221].

Causative agents either remain extracellularly on the epithelial layer or penetrate into the epithelium (*N. gonorrhoeae* and *C. trachomatis*) and cause pyogenic infection. Although arising from urethritis, chlamydiae and gonococci can spread further through the urogenital tract to cause epididymitis in men or cervicitis, endometritis and salpingitis in women [222].

Mucopurulent or purulent discharge, dysuria and urethral pruritus are symptoms of urethritis. However, many infections of the urethra are asymptomatic.

*3.10.3 **Evidence Questions***

1. In patients with urethritis what is the best method of detecting the causative pathogen?
2. In patients with urethritis what are the best treatment strategies for clinical or microbiological cure?

*3.10.4 **Evidence Summary***

A systematic search of the literature form January 2014 until February 2019 identified 488 titles of which 71 were selected for full text review. Thirteen systematic reviews or guidelines based on systematic literature searches [220-232], and seventeen original publications [233-249] were selected for further analysis. In addition, a further eleven relevant publications were identified from the references of the reviewed literature [250-260].

*3.10.5 **Diagnostic evaluation***

In symptomatic patients the diagnosis of urethritis can be made based on the presence of any of the following criteria [221, 222]:

- Mucoid, mucopurulent, or purulent urethral discharge.
- Gram or methylene-blue stain of urethral secretions demonstrating inflammation. Five or more polymorphonuclear leucocytes (PMNL) per high power field (HPF) is the historical cut-off for the diagnosis of urethritis. A threshold of ≥ 2 PMNL/HPF was proposed recently based on better diagnostic accuracy [237, 250-252], but this was not supported by other studies [236]. Therefore, in line with the 2016 European Guideline on the management of NGU [221] the use of ≥ 5 PMNL/HPF cut-off level is recommended until the benefit of alternative cut-off levels is confirmed.
- The presence of ≥ 10 PMNL/HPF in the sediment from a spun first-void urine sample or a positive leukocyte esterase test in first-void urine.

Evidence of urethral inflammation in the Gram stain of urethral secretions with gonococci located intracellularly as Gram-negative diplococci indicates GU. Non-gonococcal urethritis is confirmed when staining of urethral secretions indicates inflammation in the absence of intracellular diplococci. Clinicians should always perform point-of-care diagnostics (e.g. Gram staining, first-void urine with microscopy, leukocyte esterase testing) if available to obtain objective evidence of urethral inflammation and to guide treatment [221, 222, 235]. Recent studies showed that processing time of point-of-care diagnostics is highly relevant in terms of patient compliance and real-life applicability [233, 234].

Men who meet the criteria for urethritis should be tested for *C. trachomatis, M. genitalium and N. gonorrhoea* with nucleic acid amplification tests (NAAT), even if point-of-care tests are negative for gonorrhoeae [221, 224]. The sensitivity and specificity of NAATs is better than that of any of the other tests available for the diagnosis of chlamydial and gonococcal infections [225, 253]. The performance of first-catch urine is non-inferior to urethral swabs [253]. In case of delayed treatment, if a NAAT is positive for gonorrhoea, a culture using urethral swabs should be performed before treatment to assess the antimicrobial resistance profile of the infective strain [222]. *N. gonorrhoeae and C. trachomatis* cultures are mainly used to evaluate treatment failures and monitor developing resistance to current treatment. *Trichomonas* spp. can usually be identified microscopically [222] or by NAATs [227].

Non-gonococcal urethritis is classified as persistent when symptoms do not resolve within three to four weeks following treatment. When this occurs NAATs should be performed for urethritis pathogens including *T. vaginalis* four weeks after completion of therapy [221, 238].

*3.10.6 **Disease management***

For severe urethritis empirical treatment should be started following diagnosis. If the patients symptoms are mild, delayed treatment guided by the results of NAATs is recommended. All sexual partners at risk should be assessed and treated whilst maintaining patient confidentiality [221, 241].

3.10.6.1 Gonococcal urethritis

For GU, a combination treatment using two antimicrobials with different mechanisms of action is recommended to improve treatment efficacy and to hinder increasing resistance to cephalosporins [222]. Ceftriaxone 1 g intramuscularly or intravenously with azithromycin 1 g single oral dose should be used as first-line treatment. Azithromycin is recommended because of its favourable susceptibility rates compared to other antimicrobials, good compliance with the single-dose regimen and the possibility of a *C. trachomatis* co-infection [222]. In case of azithromycin allergy, doxycycline can be used instead in combination with ceftriaxone or cefixime [222]. A 400 mg oral dose of cefixime is recommended as an alternative regimen to ceftriaxone; however, it has less favourable pharmacodynamics and may lead to the emergence of resistance [223, 259].

A number of alternative regimens for the treatment of GU have been studied. In a randomised, open label, non-comparative clinical study dual treatment with a combination of intramuscular gentamicin 240 mg plus oral azithromycin 2 g (n=202) single doses and a combination of oral gemifloxacin 320 mg plus oral azithromycin 2 g (n=199) single doses were associated with microbiological cure rates of 100% and 99.5%, respectively [255]. A 2014 systematic review focusing on the use of single-dose intramuscular gentamicin concluded that there is insufficient data to support or refute the efficacy and safety of this regimen in the treatment of uncomplicated gonorrhoea [229]. In three prospective single arm studies enrolling men with GU the use of extended-release azithromycin 2 g single oral dose resulted in microbiological cure rates of 83% (n=36), 93.8% (n=122) and 90.9% (n=33), respectively [245, 246, 248]. However, azithromycin monotherapy is generally not recommended because of its effect on increasing macrolide resistance rates [222]. Intramuscular spectinomycin 2 g single dose shows microbiological cure rates above 96% [256, 259] in urogenital gonorrhoeal infections where available, it can be a valid treatment alternative. An open label, randomised trial compared oral fosfomycin trometamol 3 g on days one, three and five (n=60) with intramuscular ceftriaxone 250 mg plus oral azithromycin 1 g single dose (n=61) in men with uncomplicated GU. In the per-protocol analysis clinical and microbiologic cure rates were 96.8% and 95.3% respectively [249].

The worldwide increase in gonorrhoeal antimicrobial resistance and the emergence of multidrug-resistant gonorrhoeal strains is a globally recognised healthcare crisis which emphasises the importance of guideline adherence [228, 240, 260].

3.10.6.2 Non-gonococcal urethritis

For NGU without an identified pathogen oral doxycycline 100 mg twice daily for seven days should be used as first-line treatment. Alternatively, single dose oral azithromycin 500 mg day one and 250 mg days two to four can be used. This regimen provides better efficacy compared to azithromycin 1 g single dose for *M. genitalium* infections, in which azithromycin 1 g single dose treatment is associated with the development of increasing macrolide resistance significantly decreasing the overall cure rate [221, 224, 230, 244]. However, a retrospective cohort study did not find significant difference between the extended and 1 g single dose azithromycin regimen regarding cure rates and the selection of macrolide resistance in *M. genitalium* urethritis [242]. If macrolide resistant *M. genitalium* is detected moxifloxacin 400 mg can be used for seven to fourteen days [221, 222, 231]. In case of failure after both azithromycin and moxifloxacin treatment, pristinamycin (registered in France) is the only antimicrobial agent with documented activity against *M. genitalium* [224, 243, 254]. Josamycin 500 mg three times a day for ten days is used in Russia, but will not eradicate macrolide-resistant strains [224].

For chlamydial urethritis azithromycin 1 g single dose and doxycycline 100 mg twice daily for seven days are both effective options [258]. A Cochrane review found that in men with urogenital *C. trachomatis* infection regimens with azithromycin are probably less effective than doxycycline for microbiological failure, however, there might be little or no difference for clinical failure [232]. Fluoroquinolones, such as ofloxacin or levofloxacin, may be used as second-line treatment only in selected cases where the use of other agents is not possible [257].

For *U. urealyticum* infections the efficacy of doxycycline 100 mg twice daily for seven days is similar to azithromycin 1 g single dose treatment [221, 239]. For urethritis caused by *T. vaginalis* oral metronidazole or tinidazole 2 g single dose is recommended as first-line treatment. For treatment options for persistent or recurrent *T. vaginalis* infection refer to the review of Sena *et. al.*, [227]. In case of persistent NGU treatment should cover *M. genitalium* and *T. vaginalis* [221, 222].

3.10.7 ***Follow-up***

Patients should be followed-up for control of pathogen eradication after completion of therapy only if therapeutic adherence is in question, symptoms persist or reoccurrence is suspected. Patients should be instructed to abstain from sexual intercourse for seven days after therapy is initiated, provided their symptoms have resolved and their sexual partners have been adequately treated. Reporting and source tracing should

be done in accordance with national guidelines and in cooperation with specialists in venereology, whenever required. Persons who have been diagnosed with a new STD should receive testing for other STDs, including syphilis and HIV [226].

3.10.8 Summary of evidence and recommendations for the diagnostic evaluation and antimicrobial treatment of urethritis

Summary of evidence	**LE**
A Gram stain of urethral discharge or a urethral smear that shows ≥ 5 leukocytes per high power field (× 1,000) and gonococci located intracellularly as Gram-negative diplococci, indicates gonococcal urethritis.	3b
Validated NAATs of first-void urine samples have better sensitivity and specificity than any of the other tests available for the diagnosis of chlamydial and gonococcal infections.	2a
For GU dual treatment with ceftriaxone and azithromycin is the most effective combination.	2a
In case of urogenital *C. trachomatis* infection in men azithromycin is probably less effective than doxycycline for microbiological failure, however, there might be little or no difference for clinical failure.	1a
In case of *U. urealyticum* infection the efficacy of doxycycline 100 mg twice for seven days is similar to azithromycin 1 g single dose treatment.	2a

Recommendations	**Strength rating**
Perform a Gram stain of urethral discharge or a urethral smear to preliminarily diagnose gonococcal urethritis.	Strong
Perform a validated nucleic acid amplification test (NAAT) on a first-void urine sample or urethral smear prior to empirical treatment to diagnose chlamydial and gonococcal infections.	Strong
Delay treatment until the results of the NAATs are available to guide treatment choice in patients with mild symptoms.	Strong
Perform a urethral swab culture, prior to initiation of treatment, in patients with a positive NAAT for gonorrhoea to assess the antimicrobial resistance profile of the infective strain.	Strong
Use a pathogen directed treatment based on local resistance data.	Strong
Sexual partners should be treated maintaining patient confidentiality.	Strong

Table 8: Suggested regimens for antimicrobial therapy for urethritis

Pathogen	Antimicrobial	Dosage & Duration of therapy	Alternative regimens
Gonococcal Infection	Ceftriaxone Azithromycin	1 g i.m. or i.v., SD 1 g p.o., SD	• Cefixime 400 mg p.o., SD plus Azithromycin 1 g p.o., SD In case of cephalosporin allergy: • Gentamicin 240 mg i.m SD plus Azithromycin 2 g p.o., SD • Gemifloxacin 320 mg p.o., SD plus Azithromycin 2 g p.o., SD • Spectinomycin 2 g i.m., SD • Fosfomycin trometamol 3 g p.o., on days 1, 3 and 5 In case of azithromycin allergy, in combination with ceftriaxone or cefixime: • Doxycycline 100 mg b.i.d, p.o., 7 days
Non-Gonococcal infection (non-identified pathogen)	Doxycycline	100 mg b.i.d, p.o., 7-10 days	Azithromycin 500 mg p.o., day 1, 250 mg p.o., 4 days
Chlamydia trachomatis	Azithromycin Or Doxycycline	1.0-1.5 g p.o., SD 100 mg b.i.d, p.o., for 7 days	• Levofloxacin 500 mg p.o., q.d., 7 days • Ofloxacin 200 mg p.o., b.i.d., 7 days
Mycoplasma genitalium	Azithromycin	500 mg p.o., day 1, 250 mg p.o., 4 days	In case of macrolide resistance: • Moxifloxacin 400 mg q.d., 7-14 days
Ureaplasma urealyticum	Doxycycline	100 mg b.i.d, p.o., 7 days	Azithromycin 1.0-1.5 g p.o., SD
Trichomonas vaginalis	Metronidazole Tinidazole	2 g p.o., SD 2 g p.o., SD	Metronidazole 500 mg p.o., b.i.d., 7 days
Persistent non-gonococcal urethritis			
After first-line doxycycline	Azithromycin plus Metronidazole	500 mg p.o., day 1, 250 mg p.o., 4 days 400 mg b.i.d. p.o., 5 days	If macrolide resistant M. genitalium is detected moxifloxacin should be substituted for azithromycin
After first-line azithromycin	Moxifloxacin plus Metronidazole	400 mg p.o. q.d., 7–14 days 400 mg b.i.d. p.o., 5 days	

SD = single dose; b.i.d = twice daily; q.d = everyday; p.o. = orally; i.m. = intramuscular.

3.11 Bacterial Prostatitis

*3.11.1 **Introduction***

Bacterial prostatitis is a clinical condition caused by bacterial pathogens. It is recommended that urologists use the classification suggested by the National Institute of Diabetes, Digestive and Kidney Diseases (NIDDK) of the National Institutes of Health (NIH), in which bacterial prostatitis, with confirmed or suspected infection, is distinguished from chronic pelvic pain syndrome (CPPS) (Table 9) [261-263].

Table 9: Classification of prostatitis and CPPS according to NIDDK/NIH [261-263]

Type	Name and description
I	Acute bacterial prostatitis (ABP)
II	Chronic bacterial prostatitis (CBP)
III	Chronic non-bacterial prostatitis – CPPS
IIIA	Inflammatory CPPS (white cells in semen/EPS/VB3)
IIIB	Non-inflammatory CPPS (no white cells in semen/EPS/VB3)
IV	Asymptomatic inflammatory prostatitis (histological prostatitis)

CPPS = chronic pelvic pain syndrome; EPS = expressed prostatic secretion;
VB3 = voided bladder urine specimen 3 (urine following prostatic massage).

*3.11.2 **Evidence Question***

In men with NIDDK/NIH Category I or II prostatitis what is the best antimicrobial treatment strategy for clinical resolution and eradication of the causative pathogen?

*3.11.3 **Evidence Summary***

A systematic literature search from 1980 until June 2017 was performed. One systematic review [264], six RCTs [265-270], two narrative reviews [271, 272], one prospective cohort study [273], two prospective cross-sectional studies [274, 275], and one retrospective cohort study [267], were selected from 856 references.

A retrospective study [276], investigated the potential role of unusual pathogens in prostatitis syndrome in 1,442 patients over a four year period. An infectious aetiology was determined in 74.2% of patients; *C. trachomatis*, *T. vaginalis* and *U. urealyticum* infections were found in 37.2%, 10.5% and 5% of patients, respectively whilst *E. coli* infection was found in only 6.6% of cases. Cross sectional studies confirmed the validity of the Meares and Stamey test to determine the bacterial strain and targeted antibiotic therapies [274, 275]. The evidence levels were very good, in particular those regarding information on atypical strains, epidemiology and antibiotic treatments.

A systematic review on antimicrobial therapy for CBP [264] compared multiple antibiotic regimens from eighteen selected studies enrolling a total of 2,196 patients. The role of fluoroquinolones as first line agents was confirmed with no significant differences between levofloxacin, ciprofloxacin and prulifloxacin in terms of microbiological eradication, clinical efficacy and adverse events. The efficacy of macrolides and tetracyclines on atypical pathogens was confirmed.

Randomised controlled trials on combined treatments [269, 270] indicated that the combination of plants/herbal extracts or PDE5Is with antibiotics may improve quality of life and symptoms in patients with CBP; however, the number of enrolled patients was inadequate to obtain definitive conclusions.

A review of treatment of bacterial prostatitis [271] indicated that the treatment of CBP is hampered by the lack of an active antibiotic transport mechanism into infected prostate tissue and fluids. The review underlined the potential effect of different compounds in the treatment of ABP and CBP on the basis of over 40 studies on the topic.

One RCT compared the effects of two different metronidazole regimens for the treatment of CBP caused by *T. vaginalis* [268]. Metronidazole 500 mg three times daily for fourteen days was found to be efficient for micro-organism eradication in 93.3% of patients with clinical failure in 3.33% of cases.

*3.11.4 **Epidemiology, aetiology and pathogenesis***

Prostatitis is a common diagnosis, but less than 10% of cases have proven bacterial infection [228]. Enterobacteriaceae, especially *E. coli*, are the predominant pathogens in ABP [277]. In CBP, the spectrum of species is wider and may include atypical micro-organisms [271]. In patients with immune deficiency or HIV infection, prostatitis may be caused by fastidious pathogens, such as *M. tuberculosis*, *Candida* spp. and other rare pathogens, such as *Coccidioides immitis*, *Blastomyces dermatitidis*, and *Histoplasma capsulatum* [278]. The significance of identified intracellular bacteria, such as *C. trachomatis*, is uncertain [279]; however, two studies have highlighted its possible role as a causative pathogen in CBP [280, 281].

*3.11.5 **Diagnostic evaluation***

3.11.5.1 History and symptoms

Acute bacterial prostatitis usually presents abruptly with voiding symptoms and distressing but poorly localised pain. It is often associated with malaise and fever. Transrectal prostate biopsy increases the risk of ABP despite antibiotic prophylaxis and antiseptic prevention procedures [265]. Chronic bacterial prostatitis is defined by symptoms that persist for at least three months [282-284]. The predominant symptoms are pain at various locations including the perineum, scrotum, penis and inner part of the leg as well as LUTS [261-263].

3.11.5.2 Symptom questionnaires

In CBP symptoms appear to have a strong basis for use as a classification parameter [285]. Prostatitis symptom questionnaires have therefore been developed to assess severity and response to therapy [285, 286]. They include the validated Chronic Prostatitis Symptom Index (CPSI); however, its usefulness in clinical practice is uncertain [273].

3.11.5.3 Clinical findings

In ABP, the prostate may be swollen and tender on DRE. Prostatic massage should be avoided as it can induce bacteraemia and sepsis. Urine dipstick testing for nitrite and leukocytes has a positive predictive value of 95% and a negative predictive value of 70% [287]. Blood culture and complete blood count are useful in ABP. Imaging studies can detect a suspected prostatic abscess [271].

In case of longer lasting symptoms CPPS as well as other urogenital and anorectal disorders must be taken into consideration. Symptoms of CBP or CPPS can mask prostate tuberculosis. Pyospermia and hematospermia in men in endemic regions or with a history of tuberculosis should trigger investigation for urogenital tuberculosis.

3.11.5.4 Urine cultures and expressed prostatic secretion

The most important investigation in the evaluation of a patient with ABP is mid-stream urine culture [271]. In CBP, quantitative bacteriological localisation cultures and microscopy of the segmented urine and expressed prostatic secretion (EPS), as described by Meares and Stamey [288], are still important investigations to categorise clinical prostatitis [274, 275]. Accurate microbiological analysis of samples from the Meares and Stamey test may also provide useful information on the presence of atypical pathogens such as *C. trachomatis*, *T. vaginalis* and *U. urealiticum* [276]. The two-glass test has been shown to offer similar diagnostic sensitivity to the four-glass test [289].

3.11.5.5 Prostate biopsy

Prostate biopsies cannot be recommended as routine work-up and are not advisable in patients with untreated bacterial prostatitis due to the increased risk of sepsis.

3.11.5.6 Other tests

Transrectal US may reveal endoprostatic abscesses, calcification in the prostate, and dilatation of the seminal vesicles; however, it is unreliable as a diagnostic tool for prostatitis [290].

3.11.5.7 Additional investigations

3.11.5.7.1 Ejaculate analysis

Performing an ejaculated semen culture improves the diagnostic utility of the four glass test [274]; however, semen cultures are more often positive than EPS cultures in men with non-bacterial prostatitis [275]. Bladder outflow and urethral obstruction should always be considered and ruled out by uroflowmetry, retrograde urethrography, or endoscopy.

3.11.5.7.2 First-void urine sample

First-void urine is the preferred specimen for the diagnosis of urogenital *C. trachomatis* infection in men by NAATs, since it is non-invasive and yet allows the detection of infected epithelial cells and associated *C. trachomatis* particles [291].

3.11.5.7.3 Prostate specific antigen (PSA)

Prostate specific antigen is increased in about 60% and 20% of men with ABP and CBP, respectively [272]. The PSA level decreases after antibiotic therapy (which occurs in approximately 40% of patients) and correlates with clinical and microbiological improvement [266]. Measurement of free and total PSA adds no practical diagnostic information in prostatitis [292].

3.11.5.8 Summary of evidence and recommendations for the diagnosis of bacterial prostatitis

Summary of evidence	LE
Urine dipstick testing for nitrite and leukocytes has a positive predictive value of 95% and a negative predictive value of 70% in patients with ABP.	3
The four-glass Meares and Stamey test is the optimum test for diagnosis of CBP. The two-glass test has been shown to offer similar diagnostic sensitivity in a comparison study.	2b
First-void urine is the preferred specimen for the diagnosis of urogenital *C. trachomatis* infection in men by NAATs.	2b
Transrectal ultrasound is unreliable and cannot be used as a diagnostic tool in prostatitis.	3
Semen culture sensitivity is reported to be approximately 50%; therefore, it is not routinely part of the diagnostic assessment of CBP.	3
Prostate specific antigen levels may be elevated during active prostatitis; therefore, PSA testing should be avoided as it offers no practical diagnostic information for prostatitis.	3

Recommendations	Strength rating
Do not perform prostatic massage in acute bacterial prostatitis (ABP).	Strong
Take a mid-stream urine dipstick to check nitrite and leukocytes in patients with clinical suspicion of ABP.	Weak
Take a mid-stream urine culture in patients with ABP symptoms to guide diagnosis and tailor antibiotic treatment.	Weak
Take a blood culture and a total blood count in patients presenting with ABP.	Weak
Perform accurate microbiological evaluation for atypical pathogens such as *Chlamydia trachomatis* or Mycoplasmata in patients with chronic bacterial prostatitis (CBP).	Weak
Perform the Meares and Stamey 2- or 4-glass test in patients with CBP.	Strong
Perform transrectal ultrasound in selected cases to rule out the presence of prostatic abscess.	Weak
Do not routinely perform microbiological analysis of the ejaculate alone to diagnose CBP.	Weak

*3.11.6 **Disease management***

3.11.6.1 Antimicrobials

Antimicrobials are life-saving in ABP and recommended in CBP. Culture-guided antibiotic treatments are the optimum standard; however, empirical therapies should be considered in all patients with ABP.

In ABP parenteral administration of high doses of bactericidal antimicrobials, such as broad-spectrum penicillins, a third-generation cephalosporin or fluoroquinolones, is recommended [293]. For initial therapy, any of these antimicrobials may be combined with an aminoglycoside [277-286, 293-297]. Ancillary measures include adequate fluid intake and urine drainage [228]. After normalisation of infection parameters, oral therapy can be substituted and continued for a total of two to four weeks [298].

Fluoroquinolones, despite the high resistance rates of uropathogens, are recommended as first-line agents in the empirical treatment of CBP because of their favourable pharmacokinetic properties [299], their generally good safety profile and antibacterial activity against Gram-negative pathogens including *P. aeruginosa* and C. trachomatis [264, 300]. However, increasing bacterial resistance is a concern. Azithromycin and doxycycline are active against atypical pathogens such as *C. trachomatis* and genital mycoplasmata [267, 276]. Levofloxacin did not demonstrate significant clearance of *C. trachomatis* in patients with CBP [301]. Metronidazole treatment is indicated in patients with *T. vaginalis* infections [268].

Duration of fluoroquinolone treatment must be at least fourteen days while azithromycin and doxycycline treatments should be extended to at least three to four weeks [267, 276]. In CBP antimicrobials should be given for four to six weeks after initial diagnosis [271]. If intracellular bacteria have been detected macrolides or tetracyclines should be given [264, 299, 302].

3.11.6.2 Intraprostatic injection of antimicrobials

This treatment has not been evaluated in controlled trials and should not be considered [303, 304].

3.11.6.3 Combined treatments

A combination of fluoroquinolones with various herbal extracts may attenuate clinical symptoms without increasing the rate of adverse events [269]. However, a combination of fluoroquinolones with vardenafil neither improved microbiological eradication rates or attenuated pain or voiding symptoms in comparison with fluoroquinolone treatment alone [270].

3.11.6.4 Drainage and surgery

Approximately 10% of men with ABP will experience urinary retention [305] which can be managed by uretheral or suprapubic catheterisation. However, recent evidence suggests that suprapubic catheterisation can reduce the risk of development of CBP [306].

In case of prostatic abscess, both drainage and conservative treatment strategies appear feasible [307]; however, the abscess size may matter. In one study, conservative treatment was successful if the abscess cavities were < 1 cm in diameter, while larger abscesses were better treated by single aspiration or continuous drainage [308].

3.11.6.5 Summary of evidence and recommendations for the disease management of bacterial prostatitis

Summary of evidence	**LE**
The treatment regimen for ABP is based on clinical experience and a number of uncontrolled clinical studies. For systemically ill patients with ABP, parenteral antibiotic therapy is preferable. After normalisation of infection parameters, oral therapy can be substituted and continued for a total of two to four weeks.	3
The role of fluoroquinolones as first-line agents for antimicrobial therapy for CBP was confirmed in a systematic review, with no significant differences between levofloxacin, ciprofloxacin and prulifloxacin in terms of microbiological eradication, clinical efficacy and adverse events.	1a
Metronidazole 500 mg three times daily for fourteen days was found to be efficient for eradication in 93.3% of patients with *T. vaginalis* CBP.	1b
In patients with CBP caused by obligate intracellular pathogens, macrolides showed higher microbiological and clinical cure rates compared to fluoroquinolones.	1a
Clinicians should consider local drug-resistance patterns when choosing antibiotics.	3

Recommendations	**Strength rating**
Acute bacterial prostatitis	
Treat acute bacterial prostatitis according to the recommendations for complicated UTIs (see section 3.7.5).	Strong
Chronic bacterial prostatitis (CBP)	
Prescribe a fluoroquinolone (e.g. ciprofloxacin, levofloxacin) as first-line treatment for CBP.	Strong
Prescribe a macrolide (e.g. azithromycin) or a tetracycline (e.g. doxycycline) if intracellular bacteria have been identified as the causative agent of CBP.	Strong
Prescribe metronidazole in patients with *Trichomonas vaginalis* CBP.	Strong

Table 10: Suggested regimens for antimicrobial therapy for chronic bacterial prostatitis

Antimicrobial	**Daily dose**	**Duration of therapy**	**Comments**
Floroquinolone	Optimal oral daily dose	4-6 weeks	
Doxycycline	100 mg b.i.d	10 days	Only for *C. trachomatis* or mycoplasma infections
Azithromycin	500 mg once daily	3 weeks	Only for *C. trachomatis* infections
Metronidazole	500 mg t.i.d.	14 days	Only for *T. vaginalis* infections

b.i.d = twice daily; t.i.d = three times daily.

3.11.7 ***Follow-up***

In asymptomatic post-treatment patients routine urinalysis and/or urine culture is not mandatory as there are no validated tests of cure for bacterial prostatitis except for cessation of symptoms [271]. In patients with persistent symptoms and repeated positive microbiological results for sexually transmitted infectious pathogens, microbiological screening of the patient's partner/s is recommended. Antibiotic treatments may be repeated with a more prolonged course, higher dosage and/or different compounds [271].

3.12 Acute Infective Epididymitis

3.12.1 ***Evidence question***

In men with acute epididymitis what is the best antimicrobial treatment strategy for clinical resolution and eradication of the causative pathogen in:

1. men at low risk of gonorrhoea infection;
2. men at high risk of gonorrhoea infection?

3.12.2 ***Epidemiology, Aetiology and Pathophysiology***

Epididymitis is a common condition with incidence ranging from 25 to 65 cases per 10,000 adult males per year and can be acute, chronic or recurrent [309]. Acute epididymitis is clinically characterised by pain, swelling and increased temperature of the epididymis, which may involve the testis and scrotal skin. It is generally caused by migration of pathogens from the urethra or bladder. Torsion of the spermatic cord (testicular torsion) is the most important differential diagnosis in boys and young men.

The predominant pathogens isolated are *C. trachomatis*, Enterobacteriaceae (typically *E. coli*) and *N. gonorrhoeae* [310]. Men who have anal intercourse and those with abnormalities of the urinary tract resulting in bacteriuria are at higher risk of epididymitis caused by Enterobacteriaceae. The mumps virus should be considered if there are viral prodromal symptoms and salivary gland enlargement. Tuberculous epididymitis may occur, typically as chronic epididymitis, in high-risk groups such as men with immunodeficiency and those from high prevalence countries, it frequently results in a discharging scrotal sinus. *Brucella* or *Candida* spp. are rare possible pathogens.

3.12.3 ***Diagnostic Evaluation***

Culture of a mid-stream specimen of urine should be performed and any previous urine culture results should be checked. Sexually transmitted infection with *C. trachomatis* or *N. gonorrhoeae* should be detected by NAAT on first voided urine. A urethral swab or smear should be performed for Gram staining and culture if *N. gonorrhoeae* is likely [311]. Detection of these pathogens should be reported according to local procedures. All patients with probable sexually transmitted infections (STIs) should be advised to attend an appropriate clinic to be screened for other STIs. Men with Enterobacteriaceae may require investigation for lower urinary tract abnormalities. If tuberculous epididymitis is suspected, three sequential early morning urine samples should be cultured for acid-fast bacilli (AFB) and sent for screening by NAAT for *M. tuberculosis* DNA [312]. If appropriate prostate secretion, ejaculate, discharge from a draining scrotal fistula, as well as fine needle aspiration and biopsy specimens should be investigated using microscopy, AFB culture and NAAT.

3.12.4 ***Disease Management***

Men with suspected STI should be informed of the risks to others and advised not to have sex until free of infection. Empirical antimicrobial therapy has to be chosen with consideration of the most probable pathogen and degree of penetration into the inflamed epididymis and may need to be varied according to local pathogen sensitivities and guidance. Generally, both *C. trachomatis* and Enterobacteriaceae should be covered initially and the regimen modified according to pathogen identification. Doxycycline and some specific fluoroquinolones have good clinical and microbiological cure rates in patients with suspected *C. trachomatis* or *M. genitalium* and both achieve adequate levels in inflamed male genital tissues with oral dosing. Macrolide antibiotics such as azithromycin are effective against *C. trachomatis* but not tested in epididymitis. Fluoroquinolones remain effective for oral treatment of Enterobacteriaceae although resistance is increasing and local advice should be sought. Fluoroquinolones should not be considered for gonorrhoea. Single high parenteral dose of a third generation cephalosporin is effective against *N. gonorrhoeae*; current resistance patterns and local public health recommendations should guide choice of agent.

Clinical response to antibiotics in men with severe epididymitis should be assessed after approximately three days. Men with likely or proven STI should be assessed at fourteen days to check cure and ensure tracing and treatment of contacts according to local public health recommendations.

3.12.5 ***Evidence Summary***

Relating to this chapter, three guidelines based on systematic reviews were identified [311, 313, 314] with search dates of December 2009, March 2012 and April 2013, respectively. No evidence quality assessments were detailed. A structured search of the literature from January 2010 to May 2017 identified 1,108 titles of which 46 were selected for full text review and six were included [315-320]. In addition, a high quality RCT outside the search dates was identified which demonstrated that a ten-day course of ciprofloxacin was superior to pivampicillin for clinical cure (80% vs. 60%) in men aged > 40 years [321]. Data from a large comparative case series suggested that young age and history of sexual activity are not sufficiently predictive of a sexually transmitted pathogen to guide antibiotic treatment in acute epididymitis [319].

Empiric antibiotic regimens from existing guidelines [311, 313, 314] and panel consensus:

1. For men with acute epididymitis at low risk of gonorrhoea (e.g. no discharge) a single agent or combination of two agents of sufficient dose and duration to eradicate *C. trachomatis* and Enterobacteriaceae should be used. Appropriate options are:

   A. A fluoroquinolone active against C. trachomatis orally once daily for ten to fourteen days*

   OR

   B. Doxycycline 200 mg initial dose by mouth and then 100 mg twice daily for ten to fourteen days* **plus** an antibiotic active against Enterobacteriaceae** for ten to fourteen days*

2. For men with likely gonorrhoeal acute epididymitis a combination regimen active against Gonococcus and *C. trachomatis* must be used such as:

   A. Ceftriaxone 500 mg intramuscularly single dose **plus** doxycycline 200 mg initial dose by mouth and then 100 mg twice daily for ten to fourteen days*

3. For non-sexually active men with acute epididymitis a single agent of sufficient dose and duration to eradicate Enterobacteriaceae should be used. Appropriate option is a fluoroquinolone by mouth once daily for ten to fourteen days*

*Depending upon pathogen identification and clinical response.
** A parenteral option will be required for men with severe infection requiring hospitalisation.

Surgical exploration may be required to drain abscesses or debride tissue. A comparative cohort study found that lack of separation of epididymis and testis on palpation and the presence of abscess on US may predict requirement for surgery following initial antibiotic treatment [315].

A cohort study found semen parameters may be impaired during epididymitis but recovered following successful treatment [318]. Comparative clinician cohort studies suggest adherence to guidelines for assessment and treatment of epididymitis is low, particularly by urologists compared to sexual health specialists [316] and by primary care physicians [317].

*3.12.6 **Screening***

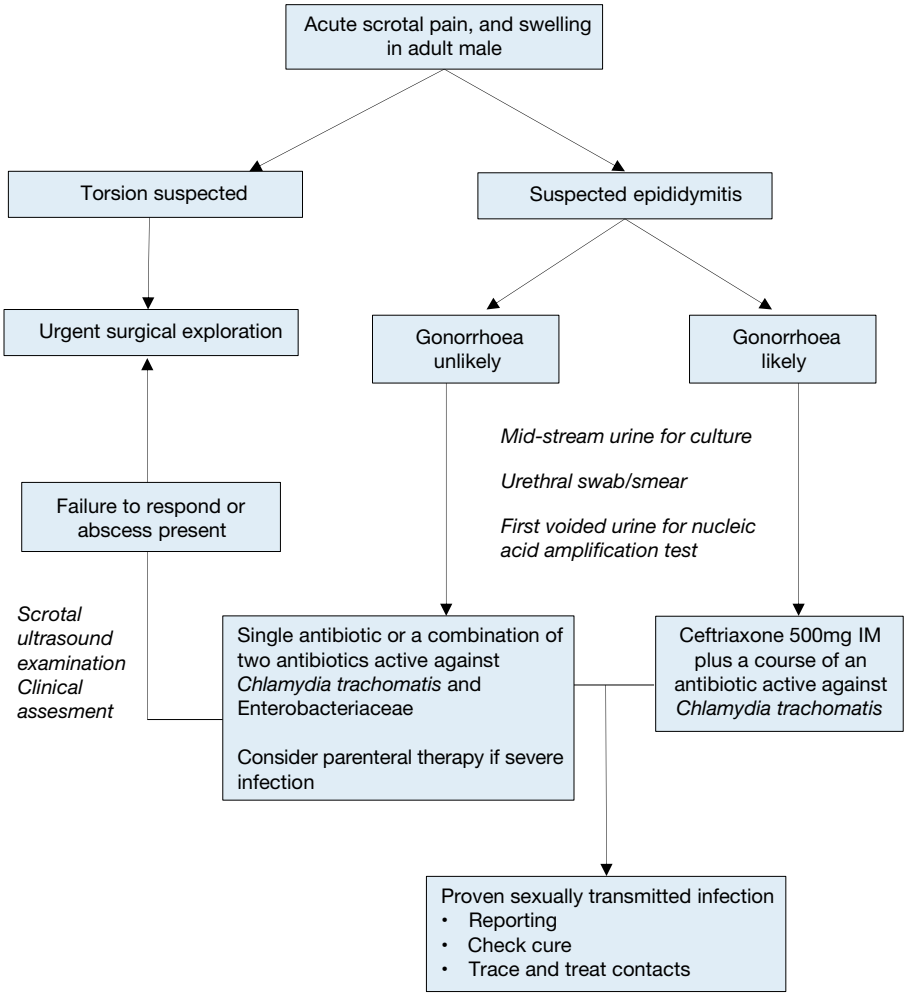
A large cohort screening study for carriage of *C. trachomatis* including a randomly selected group of 5,000 men of whom 1,033 were tested showed no benefit in terms of reduction in risk of epididymitis over nine years of observation [320].

*3.12.7 **Summary of evidence and recommendations for the diagnosis and treatment of acute infective epididymitis***

Summary of evidence	**LE**
In young sexually active patients both STIs and Enterobacteriaceae have to be considered as aetiological agents.	3
In patients > 40 years antibiotic therapy with ciprofloxacin is superior to pivmecillinam.	1b
A negative sexual risk history does not exclude STIs in sexually active men.	3

Recommendations	**Strength rating**
Obtain a mid-stream urine and a first voided urine for pathogen identification by culture and nucleic acid amplification test.	Strong
Initially prescribe a single antibiotic or a combination of two antibiotics active against *Chlamydia trachomatis* and Enterobacteriaceae in young sexually active men; in older men without sexual risk factors only Enterobacteriaceae have to be considered.	Strong
If gonorrhoeal infection is likely give single dose ceftriaxone 500 mg intramuscularly in addition to a course of an antibiotic active against *Chlamydia trachomatis*.	Strong
Adjust antibiotic agent when pathogen has been identified and adjust duration according to clinical response.	Weak
Follow national policies on reporting and tracing/treatment of contacts for sexually transmitted infections.	Strong

Figure 2: Diagnostic and treatment algorithm for adult men with acute epididymitis



3.13 Fournier's Gangrene (Necrotising fasciitis of the perineum and external genitalia)

3.13.1 Evidence questions

1. What is the best antimicrobial treatment strategy to reduce mortality?
2. What is the best debridement and reconstruction strategy to reduce mortality and aid recovery?
3. Are there any effective adjuvant treatments that improve outcome?

3.13.2 Epidemiology, Aetiology and Pathophysiology

Fournier's gangrene is an aggressive and frequently fatal polymicrobial soft tissue infection of the perineum, peri-anal region, and external genitalia [322]. It is an anatomical sub-category of necrotising fasciitis with which it shares a common aetiology and management pathway.

3.13.3 Diagnostic Evaluation

Typically, there is painful swelling of the scrotum or perineum with sepsis [322]. Examination shows small necrotic areas of skin with surrounding erythema and oedema. Crepitus on palpation and a foul-smelling exudate occurs with more advanced disease. Patient risk factors for occurrence and mortality include being immunocompromised, most commonly diabetes or malnutrition, recent urethral or perineal surgery, and high body mass index (BMI). In up to 40% of cases, the onset is more insidious with undiagnosed pain often resulting in delayed treatment [323]. A high index of suspicion and careful examination, particularly of obese patients, is required. Computed tomography or MRI can help define para-rectal involvement, suggesting the need for bowel diversion [322].

3.13.4 Disease Management

The degree of internal necrosis is usually vastly greater than suggested by external signs, and consequently, adequate, repeated surgical debridement with urinary diversion by suprapubic catheter is necessary to reduce

mortality [322]. Consensus from case series suggests that surgical debridement should be early (< 24 hours) and complete, as delayed and/or inadequate surgery may result in higher mortality [322]. Immediate empiric parenteral antibiotic treatment should be given that covers all probable causative organisms and can penetrate inflammatory tissue. A suggested regime would comprise a broad-spectrum penicillin or third-generation cephalosporin, gentamicin and metronidazole or clindamycin [322]. This can then be refined, guided by microbiological culture.

*3.13.5 **Evidence Summary***

A systematic literature search from 1980 to July 2017 was performed. From 640 references one RCT [324], two systematic reviews [325, 326], one narrative review [322], three registry studies [327-329], one prospective cohort study [330] and two retrospective comparative cohort studies with at least 25 patients [331, 332] were selected. The three registry studies from the United States [327-329], found mortality rates of 10%, 7.5% and 5% from 650, 1,641 and 9,249 cases, respectively. Older age, diabetes and high BMI were associated with higher risk. A prospective cohort study showed that disease-specific severity scores did predict outcome, but were not superior to generic scoring systems for critical care [330]. Concerning the evidence questions:

1. A low quality retrospective case series [331] with 168 patients found no significant difference in mortality between patients given ≤ 10 days of parenteral antibiotics (80 patients) and those given > 10 days (88 patients).
2. A systematic review of wound closure techniques [326] found low-quality evidence from 16 case series involving 425 male patients. They recommended primary or secondary wound closure for scrotal defects ≤ 50% with the use of flaps or skin grafts for defects involving > 50% of the scrotum or with extension outside the scrotum.
3. A systematic review on the use of hyperbaric oxygen therapy [325] included three comparative case series and four other case series. All were retrospective and published prior to 2000. No consistent evidence of benefit was found; an RCT was advised. A more recent comparative case series [332] suggested benefit for use of hyperbaric oxygen therapy in 16 patients compared to 12 cases without use of such therapy in terms of reduced mortality and fewer debridements (low quality evidence). A low-quality RCT [324] with 30 patients found that use of honey soaked dressings resulted in a shorter hospital stay (28 vs. 32 days) than dressing soaked with Edinburgh solution of lime (EUSOL). We found no evidence of benefit for use of negative-pressure (vacuum) wound therapy in Fournier's gangrene.

*3.13.6 **Summary of evidence and recommendations for the disease management of Fournier's Gangrene***

Summary of evidence	**LE**
Immediate empiric parenteral antibiotic treatment should be given that covers all probable causative organisms and can penetrate inflammatory tissue.	3
A systematic review of wound closure techniques recommended primary or secondary wound closure for scrotal defects ≤ 50% with the use of flaps or skin grafts for defects involving > 50% of the scrotum or with extension outside the scrotum.	3
No consistent evidence of benefit for hyperbaric oxygen therapy was found.	3
A low quality RCT found that dressings soaked in honey resulted in a shorter hospital stay than dressing soaked with EUSOL.	3
No evidence of benefit for use of negative-pressure (vacuum) wound therapy in Fournier's gangrene was found.	4

Recommendations	**Strength rating**
Start treatment for Fournier's gangrene with broad-spectrum antibiotics on presentation, with subsequent refinement according to culture and clinical response.	Strong
Commence repeated surgical debridement for Fournier's gangrene within 24 hours of presentation.	Strong
Do not use adjunctive treatments for Fournier's gangrene except in the context of clinical trials.	Weak

Table 11: Suggested regimens for antimicrobial therapy for Fournier's Gangrene of mixed microbiological aetiology adapted from [333]**.**

Antimicrobial	Dosage
Piperacillin-tazobactam plus Vancomycin	4.5 g every 6-8 h IV 15 mg/kg every 12 h
Imipenem-cilastatin	1 g every 6-8 h IV
Meropenem	1 g every 8 h IV
Ertapenem	1 g once daily
Gentamicin	5 mg/kg daily
Cefotaxime plus metronidazole or clindamycin	2 g every 6 h IV 500 mg every 6 h IV 600-900 mg every 8 h IV
Cefotaxime plus fosfomycin plus metronidazole	2 g every 6 h IV 5 g every 8 h IV 500 mg every 6 h IV

IV = intravenous

3.14 Peri-Procedural Antibiotic Prophylaxis

3.14.1 ***General Principles***

3.14.1.1 Definition of infectious complications

The European Centre for Disease Prevention and Control (ECDC) and the CDC have both presented similar definitions recommended for the evaluation of infectious complications [334, 335].

3.14.1.2 Non-antibiotic measures for asepsis

There are a number of non-antibiotic measures designed to reduce the risk of surgical site infection (SSI), many are historically part of the routine of surgery. The effectiveness of measures tested by RCTs are summarised in systematic reviews conducted by the Cochrane Wounds Group (http://wounds.cochrane.org/news/reviews). Urological surgeons and the institutions in which they work should consider and monitor maintenance of an aseptic environment to reduce risk of infection from pathogens within patients (microbiome) and from outside the patient (nosocomial/healthcare-associated). This should include use of correct methods of instrument cleaning and sterilisation, frequent and thorough cleaning of operating rooms and recovery areas and thorough disinfection of any contamination. The surgical team should prepare to perform surgery by effective hand washing [336], donning of appropriate protective clothing and maintenance of asepsis. These measures should continue as required in recovery and ward areas.

Patients should be encouraged to shower pre-operatively, but use of chlorhexidine soap does not appear to be beneficial [337]. Although evidence quality is low, any required hair removal appears best done by clipping, rather than shaving, just prior to incision [338]. Mechanical bowel preparation should not be used as evidence review suggests harm not benefit [339, 340]. There is some weak evidence that skin preparation using alcoholic solutions or chlorhexidine result in a lower rate of SSI than iodine solutions [341]. Studies on the use of plastic adherent drapes showed no evidence of benefit in reducing SSI [342].

3.14.1.3 Detection of bacteriuria prior to urological procedures

Identifying bacteriuria prior to diagnostic and therapeutic procedures aims to reduce the risk of infectious complications by controlling any pre-operative detected bacteriuria and to optimise antimicrobial coverage in conjunction with the procedure. A systematic review of the evidence identified eighteen studies comparing the diagnostic accuracy of different index tests (dipstick, automated microscopy, dipslide culture and flow cytometry), with urine culture as the reference standard [343]. The systematic review concluded that none of the alternative urinary investigations for the diagnosis of bacteriuria in adult patients prior to urological interventions can currently be recommended as an alternative to urine culture [343].

3.14.1.4 Choice of agent

Urologists should have knowledge of local pathogen prevalence for each type of procedure, their antibiotic susceptibility profiles and virulence in order to establish written local guidelines. These guidelines should cover the five modalities identified by the ECDC following a systematic review of the literature [344]. The agent should ideally not be one that may be required for treatment of infection. When risk of skin wound infection is low or absent, an aminoglycoside (gentamicin) should provide cover against likely uropathogens provided the eGFR is > 20 mL/min; second generation cephalosporins are an alternative [345]. Recent urine culture results including presence of any multi-resistant organisms, drug allergy, history of *C. difficile* associated diarrhoea,

recent antibiotic exposure, evidence of symptomatic infection pre-procedure and serum creatinine should be checked. The panel have decided not to make recommendations for specific agents for particular procedures as there is considerable variation in Europe and worldwide regarding bacterial pathogens, their susceptibility and availability of antibiotic agents.

3.14.2 ***Specific procedures and evidence question***

A literature search from 1980 to February 2017 identified RCTs, systematic reviews and meta-analyses that investigated the benefits and harms of using antibiotic prophylaxis prior to specific urological procedures. The available evidence enabled the panel to make recommendations concerning urodynamics, cystoscopy, stone procedures (extracorporeal shockwave lithotripsy [ESWL], ureteroscopy and percutaneous nephrolithotomy [PCNL]), transurethral resection of the prostate (TURP) and transurethral resection of the bladder (TURB). For nephrectomy and prostatectomy the scientific evidence was too weak to allow the panel to make recommendations either for or against antibiotic prophylaxis. The general evidence question was: Does antibiotic prophylaxis reduce the rate of post-operative symptomatic UTI in patients undergoing each named procedure?

3.14.2.1 Urodynamics

The literature search identified one Cochrane review with search date of December 2009 [346] and two later RCTs [347, 348]. Foon *et al.*, identified nine RCTs enrolling 973 patients with overall low quality and high or unclear risks of bias. The outcome of clinical UTI was reported in four trials with no benefit found for antibiotic prophylaxis versus placebo [RR (95%CI) 0.73 (0.52-1.03)]. A meta-analysis of nine trials showed that use of antibiotics reduced the rate of post-procedural bacteriuria [RR (95%CI) 0.35 (0.22-0.56)] [346]. Neither Hirakauva *et al.*, or Gurburz *et al.*, reported a clinical UTI outcome and had conflicting findings for reduction in risk of bacteriuria [347, 348].

3.14.2.2 Cystoscopy

The literature search identified two systematic reviews and meta-analyses with search dates of April 2014 and December 2013, respectively [349, 350]. No additional RCTs subsequent to these dates were found. Garcia-Perdomo *et al.*, included seven RCTs with a total of 3,038 participants. The outcome of symptomatic UTI was measured by five trials of moderate overall quality and meta-analysis showed a benefit for using antibiotic prophylaxis [RR (95%CI) 0.53 (0.31 – 0.90)]; ARR 1.3% (from 2.8% to 1.5%) with a NNT of 74 [350]. This benefit was not seen if only the two trials with low risk of bias were used in the meta-analysis. Carey *et al.*, included seven RCTs with 5,107 participants. Six trials were included in meta-analysis of the outcome of symptomatic bacteriuria which found benefit for use of antibiotic prophylaxis [RR (95%CI) 0.34 (0.27 – 0.47)]; ARR 3.4% (from 6% to 2.6%) with NNT of 28 [349]. Given the low absolute risk of post-procedural UTI in well-resourced countries, the high number of procedures being performed, and the high risk of contributing to increasing antimicrobial resistance the panel consensus was to strongly recommend not to use antibiotic prophylaxis in patients undergoing urethrocystoscopy (flexible or rigid).

3.14.2.3 Interventions for urinary stone treatment

3.14.2.3.1 Extracorporeal shockwave lithotripsy

For patients without bacteriuria undergoing ESWL two systematic reviews and meta-analyses were identified with latest search dates of November 2011 and October 2012, respectively [351, 352]. The literature search to February 2017 identified one further trial [353]. Lu *et al.*, included nine RCTs with a total of 1,364 patients and found no evidence of benefit in terms of reducing the rate of post-procedural fever or bacteriuria [351]. Mrkobrada *et al.*, included eight RCTs with a total of 940 participants and found no evidence of benefit for antibiotic prophylaxis to reduce rate of fever or trial-defined infection [352]. The RCT reported by Hsieh *et al.*, with 274 patients had a severe risk of bias. It found no reduction in fever at up to one week post-procedure using a single dose of levofloxacin 500 mg and no difference in the rate of bacteriuria [353].

For patients with bacteriuria or deemed at high risk of complications one RCT comparing the use of ofloxacin or trimethoprim-sulphamethoxazole for three days prior and four days subsequent to ESWL in 56 patients with ureteric stents was identified [354]. They found no difference in rate of clinical UTI at seven days (no events) and no difference in post-ESWL bacteriuria.

3.14.2.3.2 Ureteroscopy

A single systematic review [355] and two meta-analyses [356, 357] with latest search date of December 2013 were identified. Bootsma *et al.*, and Dahm *et al.*, included two low quality RCTs with a total of 233 participants and showed low-grade evidence that antibiotic prophylaxis reduced risk of bacteriuria but not of clinical UTI [355, 356]. Lo *et al.*, included four RCTs with a total of 386 patients and found no evidence of benefit in reducing rate of clinical UTI [357]. The rate of bacteruria was reduced using antibiotic prophylaxis. Panel

discussion considered that despite low quality evidence suggesting no benefit in reducing risk of clinical UTI, clinicians and patients would prefer to use prophylaxis to prevent kidney infection or sepsis. Ideally this should be examined in a robustly designed clinical study.

3.14.2.3.3 Percutaneous neprolithotomy (PNL)

A single systematic review and meta-analysis with latest search date of October 2012 was identified which addressed whether or not antibiotic prophylaxis reduce the rate of clinical urinary infection following PNL [352]. The update search to February 2017 identified no further trials. Mrkobrada *et al.*, included five RCTs with 448 participants and pooled patients undergoing PNL or ureteroscopy. They showed a moderate level of evidence that antibiotic prophylaxis was associated with a statistically significant reduction in the risk of post-procedural UTI.

Two RCTs with overall low risk of bias comparing different antibiotic regimes in PNL were identified [358, 359]. Seyrek *et al.*, compared the rate of SIRS following PNL in 191 patients receiving either a combination of sulbactam/ampicillin or cefuroxime. There was no difference in SIRS or urosepsis rates [358]. Tuzel *et al.*, investigated single dose ceftriaxone versus ceftriaxone and subsequently an oral third-generation cephalosporin until after nephrostomy catheter withdrawal at mean (SD) of 3 (1) days in 73 participants undergoing PNL. They found no difference in rate of infectious complications between the two antibiotic regimens [359]. These two studies give moderate evidence that a single dose of a suitable agent was adequate for prophylaxis against clinical infection after PNL.

3.14.2.4 Transurethral resection of the prostate

A systematic review of 39 RCTs with search date up to 2009 was identified [356]. The update search to February 2017 did not reveal any further relevant studies. Of the 39 RCTs reviewed by Dahm *et al.*, six trials involving 1,666 men addressed the risk of septic episodes, 17 trials reported procedure related fever and 39 investigated bacteriuria. Use of prophylactic antibiotics compared to placebo showed a relative risk reduction (95% CI) for septic episode of 0.51 (0.27-0.96) with ARR of 2% (3.4%-1.4%) and a NNT of 50. The risk reduction (95% CI) for fever was 0.64 (0.55-0.75) and 0.37 (0.32-0.41) for bacteriuria.

3.14.2.5 Transurethral resection of the bladder

A literature search to February 2017 found one systematic review [355] which included two trials with a total of 152 participants. No more recent RCTs were identified. The two trials found no difference in rate of bacteriuria and either had no clinical UTI events, or did not report any. The review did not attempt sub-group analysis according to presence of risk factors for post-operative infection such as tumour size. Panel discussion concluded that a weak recommendation to use antibiotic prophylaxis for patients undergoing TURB who had a high risk of suffering post-operative sepsis would be appropriate.

3.14.2.6 Transrectal prostate biopsy

3.14.2.6.1 Non-antimicrobial interventions

A meta-analysis of four studies including 671 men evaluated the use of rectal preparation by enema before transrectal biopsy. No significant advantage was found regarding infectious complications [RR (95% CIs) 0.96 (0.64 to 1.54)] [360-362].

Meta-analysis of eight trials including 1,717 men showed that use of a rectal povidone-iodine preparation before biopsy in addition to antimicrobial prophylaxis resulted in a lower rate of infectious complications [RR (95% CIs) 0.55 (0.41 to 0.72)] [363-368]. Single RCTs showed no evidence of benefit for perineal skin disinfection [369], but reported an advantage for rectal povidone-iodine preparation before biopsy compared to after biopsy [370].

No evidence was found that extended biopsy templates or use of peri-prostatic injection of local anaesthesia resulted in more infectious complications than standard templates or no injection, respectively [371].

A total of seven studies including 1,330 patients compared the impact of biopsy route on infectious complications. Infectious complications were significantly higher following transrectal biopsy (37 events among 657 men) compared to transperineal biopsy (22 events among 673 men), [RR (95% CIs) 1.81 (1.09 to 3.00)] [372-378].

3.14.2.6.2 Antimicrobial prophylaxis

A meta-analysis of eleven studies with 1,753 patients showed significantly reduced infections after biopsy when using antimicrobial prophylaxis as compared to placebo/control [RR (95% CIs) 0.56 (0.40 to 0.77)] [360, 366, 368, 379-385]; therefore, antimicrobial prophylaxis is strongly recommended.

Fluoroquinolones have been traditionally used for antibiotic prophylaxis; however, overuse and misuse of fluoroquinolones has resulted in an increase in fluoroquinolone resistance. In addition, the European

Commission has implemented stringent regulatory conditions regarding the use of fluoroquinolones for antibiotic prophylaxis in urological treatment and diagnostic interventions due to their disabling and potentially long-lasting side effects [121].

A systematic review and meta-analysis on antibiotic prophylaxis for the prevention of infectious complications following prostate biopsy concluded that in countries where fluoroquinolones are allowed as antibiotic prophylaxis, a minimum of a full one-day administration, as well as targeted therapy in case of fluoroquinolone resistance, is recommended [386]. In countries where fluoroquinolones are prohibited cephalosporins, aminoglycosides or fosfomycin can be used as individual agents. In the available RCTs, fosfomycin was superior to fluoroquinolones, but routine general use should be critically assessed due to the relevant infectious complications reported in non-randomised studies [387]. Another possibility is the use of augmented prophylaxis without fluoroquinolones, although no standard combination has been established to date.

*3.14.3 **Summary of evidence and recommendations for peri-procedural antibiotic prophylaxis***

Summary of evidence	**LE**
The outcome of clinical UTI was reported in four out of eleven RCTs with no benefit found for antibiotic prophylaxis vs. placebo in patients following filling and voiding cystometry.	1b
A meta-analysis of five trials of moderate quality showed a benefit for using antibiotic prophylaxis for the reduction of symptomatic UTI in patients undergoing cystoscopy. However, this benefit was not seen if only the two trials with low risk of bias were used in the meta-analysis.	1a
Two meta-analyses found no benefit for antibiotic prophylaxis following ESWL in terms of reducing the rate of post-procedural fever and bacteriuria or trial-defined infection in patients without bacteriuria.	1a
Two meta-analyses found no evidence of benefit for antibiotic prophylaxis prior to ureteroscopy in reducing the rate of clinical UTI; however, the rate of bacteriuria was reduced.	1a
A meta-analysis of five RCTs demonstrated a moderate level of evidence that antibiotic prophylaxis was associated with a statistically significant reduction in the risk of post-procedural UTI following PNL.	1a
Two RCTs concluded that a single dose of a suitable agent was adequate for prophylaxis against clinical infection after PNL.	1b
A systematic review of 39 RCTs concluded that antibiotic prophylaxis reduced the rate of infectious complications in men undergoing TURP.	1b
A systematic review of two RCTs found no benefit for antibiotic prophylaxis in patients undergoing TURB.	1b
Meta-analysis of six trials showed that use of a rectal povidone-iodine preparation before biopsy in addition to antimicrobial prophylaxis resulted in a lower rate of infectious complications.	1a
A meta-analysis on eleven studies with 1,753 patients showed significantly reduced infections after biopsy when using antimicrobial prophylaxis as compared to placebo/control.	1a
A meta-analysis of seven studies including 1,330 patients showed significantly reduced infectious in patients undergoing transperineal biopsy as compared to transrectal biopsy.	1a

Recommendations	**Strength rating**
Do not use antibiotic prophylaxis to reduce the rate of symptomatic urinary infection following: • urodynamics; • cystoscopy; • extracorporeal shockwave lithotripsy.	Strong
Use antibiotic prophylaxis to reduce the rate of symptomatic urinary infection following ureteroscopy.	Weak
Use single dose antibiotic prophylaxis to reduce the rate of clinical urinary infection following percutaneous nephrolithotomy.	Strong
Use antibiotic prophylaxis to reduce infectious complications in men undergoing transurethral resection of the prostate.	Strong
Use antibiotic prophylaxis to reduce infectious complications in high-risk patients undergoing transurethral resection of the bladder.	Weak
Use rectal cleansing with povidone-iodine in men prior to transrectal prostate biopsy.	Strong
Use antimicrobial prophylaxis in men prior to transrectal prostate biopsy.	Strong

Table 12: Suggested regimens for antimicrobial prophylaxis prior to urological procedures.
As stated in section 3.14.1.4 the panel have decided not to make recommendations for specific agents for particular procedures, those listed below represent possible choices only. Urologists should choose a specific antimicrobial based on their knowledge of local pathogen prevalence for each type of procedure, their antibiotic susceptibility profiles and virulence.

Procedure	Prophylaxis recommended	Antimicrobial
Urodynamics	No	N/A
Cystoscopy	No	
Extracorporeal shockwave lithotripsy	No	
Ureteroscopy	Yes	Trimethoprim Trimethoprim-sulphamethoxazole Cephalosporin group 2 or 3 Aminopenicillin plus a beta-lactamase inhibitor
Percutaneous nephrolithotomy	Yes (single dose)	
Transurethral resection of the prostate	Yes	
Transurethral resection of the bladder	Yes, in patients who have a high risk of suffering post-operative sepsis.	
Transrectal prostate biopsy	Yes	Fluoroquinolones if permitted Cephalosporins, fosfomycin, aminoglycosides, if fluoroquinolones are not permitted
